THE DYNAMICS OF GENERIC KUPERBERG FLOWS

STEVEN HURDER AND ANA RECHTMAN

ABSTRACT. In this work, we study the dynamical properties of Krystyna Kuperberg’s aperiodic flows on 3-manifolds. We introduce the notion of a “zippered lamination”, and with suitable generic hypotheses, show that the unique minimal set for such a flow is an invariant zippered lamination. We obtain a precise description of the topology and dynamical properties of the minimal set, including the presence of non-zero entropy-type invariants and chaotic behavior. Moreover, the shape type of the minimal set is not pointed movable.

1. Introduction

The “Seifert Conjecture”, as originally formulated in 1950 by Seifert in [45], asked: “Does every non-singular vector field on the 3-sphere $S^3$ have a periodic orbit?” The partial answers to this question have a long history. F.W. Wilson constructed in the 1966 work [51] a smooth flow on a plug with exactly two periodic orbits, which was used to modify a given flow on a 3-manifold to obtain one with only isolated periodic orbits. Paul Schweitzer showed in the 1974 work [44], that for any closed 3-manifold $M$, there exists a non-singular $C^1$-vector field on $M$ without periodic orbits. Schweitzer’s result suggested a modified version of Seifert’s question: “Does every non-vanishing $C^\infty$ vector field on a closed 3-manifold have a periodic orbit?” Krystyna Kuperberg showed in her celebrated 1994 work [27], that the smooth Seifert Conjecture is also false by inventing a construction of aperiodic plugs which is renowned for its simplicity, beauty and subtlety.

**Theorem 1.1** (K. Kuperberg). *On every closed oriented 3-manifold $M$, there exists a $C^\infty$ non-vanishing vector field without periodic orbits.*

The goal of this work is to understand the dynamical properties of such “Kuperberg flows”, especially the structure of their minimal sets. In the exploration of these properties, we reveal their beauty and discover the hidden complexity of the Kuperberg dynamical systems.

Let us recall the strategy of the proofs of the results cited above. A plug is a compact 3-manifold with boundary in $\mathbb{R}^3$, equipped with a flow satisfying additional conditions. The flow in a plug is assumed to be parallel to the “vertical” part of the boundary, so that it may be inserted in any coordinate chart of a 3-manifold $M$ to modify the given flow on $M$, and changes only those orbits entering and leaving the “horizontal” faces of the plug. Another assumption on the flow in a plug is that there are orbits, which are said to be trapped, which enter the plug and never exit. The closure of such an orbit limits to a compact invariant set contained entirely within the interior of the plug, thus the plug must contain at least one minimal set. In the case of the Wilson Plug, the two periodic orbits are the minimal sets.

A plug is said to be aperiodic if it contains no closed orbits. Schweitzer observed in [44] that the role of the periodic orbits in a Wilson Plug could be replaced by Denjoy minimal sets, resulting in an aperiodic plug, which could then be used to “open up” the isolated closed orbits provided by Wilson’s result. The flow in the Schweitzer Plug is only $C^1$, due to the topology of the minimal set contained in the plug, around which all trapped orbits for the flow must accumulate. Harrison constructed in [19] a modified “non-flat” embedding of the Denjoy continuum into a 3-ball, which she used to construct an aperiodic plug with a $C^2$-flow. In contrast, Handel showed in [18] that if the trapped orbits of a plug accumulate on a minimal set whose topological dimension is one and is the only invariant set for the flow in the plug, then the minimal set is surface-like: the flow restricted to the minimal set is topologically conjugated to the minimal set of a flow on a surface.

Kuperberg’s construction in [27] of aperiodic smooth flows on plugs introduced a fundamental new idea, that of “geometric surgery” on a modified version of the Wilson Plug $\mathcal{W}$, to obtain the Kuperberg Plug $\mathcal{K}$ as a quotient space, $\tau: \mathcal{W} \to \mathcal{K}$. The Wilson vector field $\mathcal{W}$ on $\mathcal{W}$ is modified to provide a smooth vector field $\mathcal{K}$ on the quotient. The flow of $\mathcal{K}$ is denoted by $\Phi_t$. This is said to be a Kuperberg flow on $\mathcal{K}$.

The periodic orbits for the Wilson flow on $\mathcal{W}$ get “cut-open” when they are mapped to $\mathcal{K}$, and there they become trapped orbits for $\Phi_t$. The essence of the novel strategy behind the aperiodic property of $\Phi_t$ is perhaps best described by a quote from the paper by Matsumoto [34]:

*We therefore must demolish the two closed orbits in the Wilson Plug beforehand. But producing a new plug will take us back to the starting line. The idea of Kuperberg is to let closed orbits demolish themselves. We set up a trap within enemy lines and watch them settle their dispute while we take no active part.*

The images in $\mathcal{K}$ of the cut-open periodic orbits from the Wilson flow $\Psi_t$ on $\mathcal{W}$, generate two orbits for the Kuperberg flow $\Phi_t$ on $\mathcal{K}$, which are called the special orbits for $\Phi_t$. These two special orbits play an absolutely central role in the study of the dynamics of a Kuperberg flow.
There followed after Kuperberg’s seminal work, a collection of three works explaining in further detail the proof of the aperiodicity for the Kuperberg flow, and investigating its dynamical properties:

- the Séminaire Bourbaki lecture [17] by Étienne Ghys;
- the notes by Shigenori Matsumoto [34] in Japanese, later translated into English;

It was observed in these works that the special orbits in $K$ each limit to the other, and that a Kuperberg flow has a unique minimal set, which we denote by $\Sigma$. The topological and dynamical properties of the minimal sets for the Wilson, Schweitzer and Harrison Plugs are fundamental aspects of the constructions of the flows in these plugs. For the Kuperberg flow, the minimal set $\Sigma$ is not specified by the construction, but rather its topological properties are a consequence of the strong interaction of the special orbits. We will see that with the proper geometric assumptions in the construction of $K$, we are able to obtain a detailed understanding of the topological and dynamical properties of the minimal set $\Sigma$ as a result.

The Radius Inequality, stated as hypothesis (K8) in Section 3, is a topological property of the insertion maps used to construct the quotient space $K$ from the Wilson Plug $W$. It is an absolutely remarkable aspect of Kuperberg’s construction, that the Radius Inequality is essentially all that is required to show that the quotient flow $\Phi_t$ is aperiodic. Moreover, the smooth insertion maps which satisfy hypothesis (K8) admit many variations in their local behavior near the special orbits for the Wilson flow, with each choice yielding an aperiodic “Kuperberg flow”.

In order to describe the generic hypotheses that we introduce, we require some notions which are described more precisely in Sections 2, 3 and 4. The modified Wilson Plug $W$, as defined in Section 2, contains a cylinder set $R \subset W$ which is invariant under the Wilson flow $\Psi_t$ on $W$, and the boundary of $R$ consists of the periodic orbits for the flow. There is a “notched” subset $R' \subset R$, illustrated in Figure 18, which maps to a closed subset $\tau(R') \subset K$ by the quotient map $\tau: W \to K$, as illustrated in Figure 24. The $\Phi_t$-flow of $\tau(R')$ is a non-compact, embedded surface, $M_0 \subset K$, with boundary consisting of the special orbits in $K$. Thus, the closure $\bar{M} = \overline{M_0}$ is a flow invariant, compact connected subset of $K$, which contains the closure of the special orbits, hence as observed in [17, 28, 34], the minimal set $\Sigma \subset \bar{M}$. The existence of this compact subset $\bar{M}$ which is invariant for the Kuperberg flow $\Phi_t$ is a remarkable consequence of the construction, and is the key to a deeper understanding of the dynamical properties of the flow $\Phi_t$.

This work introduces several new concepts and techniques which are used in the study of the space $\bar{M}_0$ and its closure $\bar{M}$. The first is the notion of propellers, which are surfaces with boundary, possibly minus a point at infinity, embedded in $W$ so that they wrap around the core cylinder $R$ in the Wilson Plug $W$, as illustrated in Figure 19. The projections of these surfaces to $K$ are assembled according to the dynamics of the Kuperberg flow, to yield the embedded surface $\bar{M}_0$ as partially illustrated in Figure 28.

The study of the topological structure of $\bar{M}_0$ reveals the fundamental role played by the local dynamics of the flow $\Phi_t$ in a small open neighborhood of the core cylinder $\tau(R') \subset K$, and especially in sufficiently small open $\epsilon$-neighborhoods of the special orbits along the boundary of $\tau(R')$. In fact, we show in Proposition 9.16 that the return times of a Kuperberg flow to these $\epsilon$-neighborhoods form a syndetic set, so that the global dynamics of $\Phi_t$ is essentially determined by its local dynamics in $\epsilon$-neighborhoods of $\tau(R')$. The local dynamics of $\Phi_t$ depend on the choices made constructing the Wilson vector field $W$ on $W$ and the Kuperberg vector field $K$ on $K$. We formulate generic conditions on the choice of $W$ and the construction of $K$, in order to eliminate pathologies in the dynamics of the flows for $W$ and $K$ that may otherwise be possible.

The first type of generic condition is given by Hypothesis 12.2. In brief, this states that the vertical component of the Wilson vector field $W$ has quadratic vanishing along the periodic orbits. The anti-symmetry imposed on the modified Wilson vector field $W$ forces the generic case to be a quadratic vanishing condition.

The second type of generic condition is imposed on the insertion maps $\sigma_i$ for $i = 1, 2$ which are introduced in Section 3 as part of the construction of the space $K$. These maps are required to satisfy the Radius Inequality, in order to obtain an aperiodic flow on $K$, but the smooth properties of these maps also control many other aspects of the global dynamics of $\Phi_t$. For example, the propellers associated to the flow $\Phi_t$ which form $\bar{M}_0$ are
generated by the images of curves under the embedding maps \( \sigma_i \) and their inverses, and without assumptions on the geometries of these curves, it seems impossible to control the geometry of the space \( \mathcal{M}_0 \). The precise statements of the “generic hypotheses” we impose requires various preliminary notations, and are formally given in Definition 17.3. In brief, they assert that the insertion maps \( \sigma_i \) are “uniformly quadratic” in an open neighborhood of each periodic orbit.

We say that a Kuperberg flow \( \Phi_t \) is generic if it satisfies the conditions of Definition 17.3, which includes the quadratic hypotheses on the Wilson flow in Hypothesis 12.2. The goal of this work is then to make a complete investigation of the dynamical properties of generic Kuperberg flows.

We next discuss the results of this work. First, two natural problems concerning the topological dynamics of the flow \( \Phi_t \) are to identify its wandering set \( \mathcal{W} \) and its non-wandering set \( \Omega \), which are defined in Section 8. The minimal set \( \Sigma \) is always contained in the non-wandering set, and we show in Theorem 16.1 that:

**THEOREM 1.2.** Let \( \Phi_t \) be a Kuperberg flow of \( K \) which satisfies Hypothesis 12.2. Then the non-wandering set \( \Omega \) is a subset of the closure \( \mathcal{M} \) of the embedded manifold \( \mathcal{M}_0 \), and thus the complement of \( \mathcal{M} \) consists of wandering points for the flow.

With the additional hypothesis that the flow is generic, then Theorem 17.1 shows that the minimal set \( \Sigma \) equals the non-wandering set \( \Omega \), and we have:

**THEOREM 1.3.** Let \( \Phi_t \) be a generic Kuperberg flow of \( K \), then \( \Sigma = \Omega = \mathcal{M} \).

The papers \[17\] and \[28\] gave examples where the minimal set \( \Sigma \) equals the space \( \mathcal{M} \), and suggested that the inclusion \( \Sigma \subseteq \mathcal{M} \) may be an equality in more generality than the examples they gave. The proof of Theorem 1.3 is inspired by the examples and related remarks in these works.

It was remarked above that the topological properties of the minimal set \( \Sigma \) are a consequence of the “strong interaction” of the special orbits. The identification \( \Sigma = \mathcal{M} \) for a generic flow \( \Phi_t \) allows to make this remark precise, using the structure theory for the space \( \mathcal{M} \) that we develop in this work.

Consider the submanifold \( \mathcal{M}_0 \subset K \) as a stratified space, with the interior being a stratum of topological dimension 2, and the boundary curves (the special orbits) being a stratum of topological dimension 1. Thus, the closure \( \mathcal{M} \) of \( \mathcal{M}_0 \) inherits a type of stratified structure, where the 2-dimensional stratum of \( \mathcal{M} \) are the leaves of a laminated structure on a subset of \( \mathcal{M} \), obtained from the closure in \( K \) of the interior of \( \mathcal{M}_0 \). The 1-dimensional stratum of \( \mathcal{M} \) can be described as the boundaries of the “leaves” of the “lamination” \( \mathcal{M} \). Difficulties arise from this description though, as the special orbits for \( \Phi_t \) are the two boundary components of the manifold \( \mathcal{M}_0 \), which are dense in \( \mathcal{M} \) for a generic flow. That is, the 1-stratum of \( \mathcal{M} \) is dense in the 2-stratum, which is not a normal property for a lamination.

In fact, we show in Theorem 19.1 that for a generic Kuperberg flow, the space \( \mathcal{M} \) has a stronger property than these informal observations, in that it satisfies the conditions in Definition 19.3 which gives it a local product structure, which is analogous to that of a lamination. We call this type of structure a zippered lamination, as it is “sewn together” along the special boundary orbits.

**THEOREM 1.4.** For a generic Kuperberg flow, the space \( \mathcal{M} \) has the structure of a zippered lamination with 2-dimensional leaves.

The basis of many of our results concerning \( \mathcal{M} \), including the proof of Theorem 1.4 above, is a detailed structure theory for \( \mathcal{M}_0 \) based on the properties of finite or infinite, simple or double propellers, arising from either boundary or interior notches in \( \mathcal{M}_0 \). The amazing complexity of these aspects of the embedding of \( \mathcal{M}_0 \) in \( K \) are organized using the level function on \( \mathcal{M}_0 \), which is introduced in this work.

The notion of the relative level of two points along the same orbit of the Kuperberg flow was introduced by Kuperberg in \[27\], and is a key technique for showing that the flow obtained is aperiodic. It is defined by equations (12) and (13) in Section 4 below. Further properties of the concept of relative level were developed by Ghys and Matsumoto in \[17, 34\]. In Section 12 we show that the relative level function along orbits induces
a well-defined level function on $M_0$, for which the Reeb cylinder $\tau(\mathcal{R})$ is at level 0. The level function on $M_0$ is used to decompose this space into an infinite union of propellers $M_\ell$ for $\ell \geq 1$, where $M_\ell$ consists of sets at level $\ell$: for $\ell = 1$ this set is composed by two non-compact propellers attached to $\tau(\mathcal{R})$, while $M_\ell$ for $\ell \geq 2$ is formed by $2^\ell$ families of compact propellers. The level decomposition of $M_0$ is used to analyze its geometry and dynamics, and consequently also that of $M$.

One of the original motivations for this work was a question posed by Krystyna Kuperberg concerning the topological shape of the minimal set $\Sigma$ for the flow $\Phi_t$. Section 23 gives a very brief introduction to shape theory, including the definitions of “stable shape” in Definition 23.3 and for a continua to be “movable” or “pointed movable” in Definitions 23.5 and 23.6. It is a simple observation that the subspaces $M$ and its dense subset $M_0$ have the same topological shape, and thus for a generic flow, we can use the level decomposition of $M_0$ to study the shape of the minimal set $\Sigma$. We show in Theorems 23.4 and 23.10 as a cumulation of the results in this work:

**Theorem 1.5.** For a generic Kuperberg flow, the minimal set $\Sigma$ does not have stable shape, and is not pointed movable.

Proving that a continua does not satisfies the Mittag-Leffler condition for homology groups, is a strategy to prove that it is not movable. We introduce the Mittag-Leffler condition for homology groups in Proposition 23.7 and we show in Theorem 23.9 that:

**Theorem 1.6.** For a generic Kuperberg flow, the minimal set $\Sigma$ satisfies the Mittag-Leffler condition for homology groups.

Theorem 1.6 does not imply the stronger conclusion that $\Sigma$ is movable.

The proofs of Theorems 1.5 and 1.6 are based on Proposition 23.21 which shows that the shape of $\Sigma$ is defined by a decreasing nested sequence of compact domains $\mathcal{N}_\ell \subset \mathcal{K}$ for $\ell \geq 0$, such that each $\mathcal{N}_\ell$ satisfies $\mathcal{N}_\ell \subset \mathcal{N}_{\ell+1}$ and has the homotopy type of a finite $CW$-complex. The spaces $\mathcal{N}_\ell$ are constructed using the level function on $M_0$ and the observation in Section 13 that the double propellers introduced there are nested. That is, the double propellers at level $\ell + 1$ are contained in the closures of the interiors of double propellers at level $\ell$. We show that the fundamental groups of the spaces $\mathcal{N}_\ell$ have ranks which grow without bound with $\ell$, proving that the shape of $\Sigma$ is not stable. We then prove that the Mittag-Leffler condition for pointed spaces is not satisfied, implying that $\Sigma$ is not pointed movable. Finally, we prove that the Mittag-Leffler condition is satisfied by $\Sigma$.

Our final collection of results concern the entropy invariants and dynamical complexity of a Kuperberg flow $\Phi_t$. The topological entropy of a Kuperberg flow is zero, for as noted by Ghys in [17], this follows as a consequence of a result of Katok on $C^2$-flows on 3-manifolds in [24], which implies that the entropy of an aperiodic smooth flow on a 3-manifold must be zero. Katok’s proof in [24] uses the Pesin Theory for smooth flows, for example as given in [1], to conclude from $h_{top}(\Phi_t) > 0$ that $\Phi_t$ must have a periodic orbit.

Note that Theorem 1.2 above shows that the non-wandering set of $\Phi_t$ is contained in $M$, and hence the flow entropy $h_{top}(\Phi_t) = h_{top}(\hat{\Phi}_t|M)$, where the latter is the entropy for the flow restricted to $M$. This naturally suggests the question, whether some geometric property of $M$ may directly imply that $h_{top}(\Phi_t|M) = 0$?

It is a standard technique for the study of the dynamics of flows, to choose a section to the flow and study the dynamics of the induced return maps. There is a natural choice of “section” for the Kuperberg flow $\Phi_t$, given by the rectangle $R_0 \subset \mathcal{K}$ defined by (25) in Section 9. There is a well-defined “return map” $\hat{\Phi}$ to $R_0$ for the flow $\Phi_t$. However, the vector field $K$ is tangent to $R_0$ along the center horizontal line, which complicates the study of the dynamics for $\hat{\Phi}$. For this reason, we introduce in Section 9 the pseudogroup $G_K$ generated by the return map $\hat{\Phi}$ restricted to open subsets of $R_0$ on which the map is continuous.

We show in Section 9 that the global dynamics of the Kuperberg flow is determined by the actions of the generators for $G_K$. In particular, the compact set $M_{R_0} = M \cap R_0$ is locally invariant under the return map $\hat{\Phi}$, and so is invariant under the local actions of elements of $G_K$. The space $M_{R_0}$ is the closure of the set
\( \mathcal{M}_0 \cap \mathbb{R}_0 \), and it turns out that for the collection of special generating maps \( G^{(1)}_K \subset \mathcal{G}_K \) as defined in (146), the action of these generators on \( \mathcal{M}_0 \cap \mathbb{R}_0 \) has a systematic description in terms of the level decomposition for the propellers in \( \mathcal{M}_0 \). This is discussed in Section 13.

Even more is true. The action of the set \( G^{(1)}_K \) on the space \( \mathcal{M}_0 \cap \mathbb{R}_0 \) has a description in terms of a Cayley graph for the pseudogroup, as described in Section 14. Choosing a Riemannian metric on the Kuperberg plug, induces a metric on \( \mathcal{M}_0 \) for which this space is quasi-isometric to a tree \( T_\Phi \), with valence at most 4. The notation system for the level decomposition of \( \mathcal{M}_0 \) also labels the vertices of the embedded tree \( T_\Phi \subset \mathcal{M}_0 \). The properties of the tree model for the dynamics of \( \mathcal{G}_K \) are discussed further in Sections 14 and 22.

Section 20 introduces the entropy associated to a finite symmetric set of generators for a pseudogroup, following the ideas introduced by Ghys, Langevin and Walczak in [16]. To obtain entropy invariants of \( \Phi_t \), it is necessary to choose a finite symmetric generating set in \( \mathcal{G}_K \). We work with two such choices:

- The collection \( G^{(1)}_K \) defined in (135), with associated entropy \( h_{GLW}(G^{(1)}_K \mathcal{M}_0) \).
- The collection \( G^{(1)}_K \) defined in (146), with associated entropy \( h_{GLW}(G^{(1)}_K \mathcal{M}_0) \).

The results in Section 20 yield the implications:

\[
(1) \quad h_{top}(\Phi_t|\mathcal{M}) > 0 \implies h_{GLW}(G^{(1)}_K \mathcal{M}_0) > 0 \implies h_{GLW}(G^{(1)}_K \mathcal{M}_0) > 0 .
\]

The structure theory of \( \mathcal{M}_0 \) and the subexponential growth estimate Corollary 14.6 are used in the proof of Theorem 20.14 to show that \( h_{GLW}(G^{(1)}_K \mathcal{M}_0) = 0 \). We thus conclude:

**Theorem 1.7.** Let \( \Phi_t \) be a generic Kuperberg flow, then \( h_{top}(\Phi_t|\mathcal{M}) = 0 \).

One of the intriguing aspects of the dynamics of the \( \mathcal{G}_K \)-action associated to a Kuperberg flow, is the presence of families of “horseshoe-like” structures, as illustrated in Figure 46, which show that the \( \Phi_t \)-orbits have a form of chaotic behavior. However, the rate of contraction for the return maps of the flow \( \Phi_t \) near the special orbits is “too slow” for this chaotic behavior to yield positive entropy, as is seen in the calculations we make in Section 20 for the proof of Theorem 1.7. We say that the flow \( \Phi_t \) has “slow chaos” near \( \mathcal{M} \).

We show in the work [22], that by varying the embeddings \( \sigma_i \) for \( i = 1, 2 \) so they no longer satisfy the Radius Inequality, then the “slow chaos” for the Kuperberg flow, becomes “rapid chaos” associated with a hyperbolic attractor for the perturbed flow. These observations imply that the construction of the Kuperberg flow \( \Phi_t \) places it at “the boundary of hyperbolicity”, in the manner of partially hyperbolic systems [2].

Another pseudogroup model for the dynamics of \( \Phi_t \) is introduced in Section 21 which is the pseudogroup \( \mathcal{G}_\mathcal{C} \) acting on the simple curves in \( \mathcal{M}_0 \mathbb{R}_0 \). This action on curves induces an action on a Cantor set \( \mathcal{C} \subset \mathcal{M}_0 \mathbb{R}_0 \) which is transverse to the leaves of the lamination \( \mathcal{M} \). The action of \( \mathcal{G}_\mathcal{C} \) on \( \mathcal{C} \) can be thought of as the “essential model” for the chaotic behavior on the flow \( \Phi_t \).

The “slow chaos” property of \( \Phi_t \) is quantified by introducing the slow lamination entropy for \( \mathcal{G}_\mathcal{C} \), denoted by \( h_{GLW}(\mathcal{G}_\mathcal{C}) \) for \( 0 < \alpha < 1 \). This invariant for a pseudogroup action, is the analog of the slow flow entropy introduced in the works of Katok and Thouvenot [23] and Cheng and Li [8]. Our main result in this section is Theorem 21.10 which relates the growth of orbits for the pseudogroup with the dynamics of the insertion maps used in the construction of \( \mathcal{K} \).

**Theorem 1.8.** Let \( \Phi_t \) be a generic Kuperberg flow. If the insertion maps \( \sigma_j \) have “slow growth” in the sense of Definition 21.11, then \( h_{GLW}(\mathcal{G}_\mathcal{C}) > 0 \).

**Remark 1.9.** Let \( \Phi_t \) be a generic Kuperberg flow satisfying Definition 21.11. The works [10] [11] suggests that \( h_{GLW}(\mathcal{G}_\mathcal{C}) > 0 \) implies the Cantor set \( \mathcal{C} \) has Hausdorff dimension at least 1/2.

One of the conclusions of the calculations in Sections 20 and 21 of the entropy for the pseudogroups associated to \( \Phi_t \), is that the quadratic vanishing of the vertical component of the Wilson vector field, as specified in Hypothesis 12.2 is a key to showing that \( h_{top}(\Phi_t|\mathcal{M}) = 0 \). Remark 1.9 is a speculation that it
may be possible to show a more direct relationship between the rate of vanishing for the Wilson field $W$ along its periodic orbits and the Hausdorff dimension of the closure $M$ of $M_0$.

If the Kuperberg vector field $K$ is constructed using a piecewise smooth Wilson vector field, with hyperbolic contracting singularities along its periodic orbits, then Theorem 21.18 states that $h_{GLW}(G_{\sigma_0}) > 0$, as a consequence of the preceding calculations, suitably adapted. Question 21.19 then poses the problem of showing that $h_{top}(\Phi_t|M) > 0$ for such flows.

It was remarked in [17, 27] that Kuperberg Plugs can also be constructed for which the manifold $K$ and its flow $K$ are real analytic. Details of this construction are given in the Ph.D. Thesis [12] of the second author. The authors expect that for real analytic flows, many of the results of this work remain valid without the generic hypotheses in Definition 17.3.

In general, there are many further questions about the dynamics of flows formed by a “Kuperberg surgery”, which is the colloquial name for the construction described in Section 3.

To conclude this introduction to our work, we explain how the paper is organized, and at the same time we summarize the properties of the dynamics of a Kuperberg Plug, making the distinction between the results which were known for a general Kuperberg flow, and those results obtained in this work.

Of course, the fundamental result is Kuperberg’s theorem, which is Theorem 1.1 above: For any choice of modified Wilson flow on $W$ as constructed in Section 2, and any pair of insertion maps $\sigma_i$ which satisfy the Radius Inequality from Section 3, the Kuperberg flow $\Phi_t$ constructed on $K$ is aperiodic. Sections 2 to 8 give a self-contained and very detailed proof of this result, which is based on a synthesis of the results of the papers [27], [17] and [34].

The papers by Ghys [17] and Matsumoto [34] include further results on the dynamics of the Kuperberg flow $\Phi_t$. In particular, they show that it has a unique minimal set $\Sigma$ contained in the interior of $K$. Also, Matsumoto showed that the Kuperberg Plug traps a set with non-empty interior. These results are also discussed and proved in Sections 2 to 8 of this work, which also establish notations and fundamental techniques required for the remaining parts of the work.

The pseudogroup $G_K$ acting on a rectangle $R_0 \subset K$ is introduced in Section 9. We choose five maps among the generators of this pseudogroup that reflect the flow dynamics near the minimal set $\Sigma$: the pseudogroup orbits are syndetic in the flow orbits of points in $\Sigma$. The choice of the rectangle is not arbitrary, as it takes advantages of the symmetries in the construction of the plugs $W$ and $K$. One unavoidable consequence of the anti-symmetry property of the Kuperberg flow, is that there must be discontinuities for the return map of the flow. The nature of these discontinuities is described in Section 9, and again later in Section 20 where they enter into the calculation of the entropy for various pseudogroups.

The set $M_0$ that is dense in $M$ is described in Sections 11 and 12, giving the definition of propeller and the decomposition of $M_0$ in level sets. The relation of this decomposition with the pseudogroup $G_K$ is explained in Section 13 with the introduction of the notion of double propellers. Double propellers play a fundamental role in the proofs of Theorems 1.5 and 1.6.

To complete the description of $M_0$ we introduce in Section 14 a graph $T_\Phi \subset M_0$, which is a tree with an additional loop added at the root point $\omega_0 \in T_\Phi$. The vertices of $T_\Phi$ are in fact defined by the action of the five special generators of $G_K$ acting on the root point $\omega_0$. We call $\mathcal{G}_K^*$ the set of words obtained by composition of the special generators. The geometric interpretation suggests an algebraic decomposition of words in $G_K^*$ as normal words: a composition of two level monotone words, that is words along which the level is only increasing or only decreasing. This simplification is described in Section 14 and is a key tool for the entropy calculations. It is also used to calculate in Section 22 the area growth rate of the special leaf $M_0$ in $M$.

In the approach to the set $M_0$ described in Section 12 we introduce and discuss two types of irregular behaviors that can arise in the description of the structure of $M_0$, and that depend on the choices made in the construction of the Kuperberg Plug (Remark 12.4). Each type of irregularity results in the existence of “double propellers” attached to $M_0$, that change the embedding of $M_0$ in a uniformly bounded way, without affecting the dynamical invariants of $M$. One type of irregularity is studied in Section 15. The second type
is more subtle and the generic hypothesis is needed to control it, hence the description and boundedness of this phenomena is discussed later in the text, in Section 18. Neither of these types of irregularities have been considered previously in the study of the Kuperberg flow.

Theorem 1.3 is proved in Section 17. The key to the proof are the estimates established in Section 17 for the orbit behavior of the return map \( \Phi \) near the critical line \( r = 2 \) in \( R_0 \). The proofs of these inequalities are based on the generic assumptions on the insertion maps. It is to be expected that some form of strong regularity hypotheses is required to prove Theorem 1.3 as its conclusion is a type of “Denjoy Theorem” for a smooth flow on a surface lamination. In fact, [28, Theorem 3] gives an example of a PL flow for which the minimal set is 1-dimensional, hence not all of \( M \). It seems reasonable to conjecture that a smooth example, not satisfying the generic hypotheses, can also be constructed for which the inclusion \( \Sigma \subset M \) is proper.

Section 16 uses the notion of double propellers to prove that the set \( M \) is the non-wandering set of the Kuperberg Plug. This result allows us to restrict the entropy calculation for the flow to \( M \), as discussed in Section 20. The calculations in this section use almost all the results of the study of the geometry and dynamical properties of the flow established in previous sections. In particular, the calculations show the usefulness of the pseudo-group \( G^*_K \) defined by the nice set of generators for \( G_K \) mentioned above. The computation of the entropy that we present uses the results and techniques from Sections 9, 14 and 16 but avoids the use of Pesin Theory for flows.

The definition of a zippered lamination is given in Definition 19.3, and Theorem 19.1 shows that for a generic flow, the space \( M \) is a zippered lamination. The holonomy pseudogroup \( G_M \) of the zippered lamination \( M \) is introduced in Section 21 and its generators are related to the five special generators of the pseudogroup \( G_K \) induced by the return map of the flow \( \Phi_t \) to the section \( R_0 \). The notable properties of \( G_M \) is that it collapses the symmetry built into the Kuperberg flow, and also that the holonomy induced by a leafwise path can give a more efficient representation of the action of words in \( G_K \). These two properties suggest the possibility of the entropy of the lamination being positive, even if the flow has zero topological entropy. In Section 21 we show that the entropy of the action of \( G_M \) vanishes as well, but under extra hypothesis on the insertion maps, we prove Theorem 1.8 implying that some chaotic behavior exist in its orbit structure anyway. In Section 22 we use normal forms of words in \( G_M \) to establish the growth type of the leaves of \( M \).

Finally Theorems 1.5 and 1.6 are proved in Section 23, using the double propellers of Section 13 to build a suitable sequence of neighborhoods of \( M \) which are used to study its shape properties.

The reader will quickly observe one of the significant contributions of this work, which is an extensive collection of illustrations which accompany the text. Many of the dynamical properties that we discuss here are difficult to grasp without these illustrations, which we hope will aid the reader to a full understanding of the beauty and complexity of the dynamics of Kuperberg flows. The approach in this paper invokes four perspectives on the dynamics of the Kuperberg flow, and the illustrations help to understand the relationship between the dynamics as analyzed using each of these viewpoints. The models of the dynamical behavior illustrated in each case are related by non-linear transformations, so that it often requires some effort to visualize the correspondence between each approach.

This paper owes a profound debt to the authors of the works [17, 27, 28, 34, 42] whose text and pictures provided many insights to the Kuperberg dynamics during the development of this work, and inspired many of the illustrations in this paper.

This work was made possible by the help of many colleagues and institutions. We thank our colleagues Alex Clark, Etienne Ghys and Krystyna Kuperberg for their insights and suggestions during the development of this work. We also thank the funding agency CONACyT of Mexico for its postdoctoral Research Fellowship support, the Mathematics Department of UIC, and the Mathematics Department of University of Chicago for its welcoming support of the second author, and the University of Strasbourg for its welcoming support of the first author. We gave numerous talks on this work during the preparation of this manuscript, we thank the colleagues that contributed with comments and questions.
Finally, the authors owe many thanks to the referee, who provided many helpful comments to improve the presentation, and to improve and correct the proofs of various results in this text.

2. The modified Wilson Plug

A 3-dimensional plug is a manifold $P$ endowed with a vector field $\mathcal{X}$ satisfying the following characteristics: The manifold $P$ is of the form $D \times [-2,2]$, where $D$ is a compact 2-manifold with boundary $\partial D$. Set

$$\partial_v P = \partial D \times [-2,2] \quad , \quad \partial_h^- P = D \times \{-2\} \quad , \quad \partial_h^+ P = D \times \{2\}$$

Then the boundary (with corners) of $P$ has a decomposition

$$\partial P = \partial_v P \cup \partial_h P = \partial_v P \cup \partial_h^- P \cup \partial_h^+ P.$$ 

Let $\frac{\partial}{\partial z}$ be the vertical vector field on $P$, where $z$ is the coordinate on $[-2,2]$. The vector field $\mathcal{X}$ on $P$ must satisfy the conditions:

(P1) vertical at the boundary: $\mathcal{X} = \frac{\partial}{\partial z}$ in a neighborhood of $\partial P$; thus, $\partial_h^- P$ and $\partial_h^+ P$ are the entry and exit regions of $P$ for the flow of $\mathcal{X}$, respectively;

(P2) entry-exit condition: if a point $(x,-2)$ is in the same trajectory as $(y,2)$, then $x = y$. That is, an orbit that traverses $P$, exits just in front of its entry point;

(P3) trapped orbit: there is at least one entry point whose entire forward orbit is contained in $P$; we will say that its orbit is trapped by $P$;

(P4) tameness: there is an embedding $i: P \to \mathbb{R}^3$ that preserves the vertical direction on the boundary $\partial P$.

A plug is aperiodic if there is no closed orbit for $\mathcal{X}$.

Note that conditions (P2) and (P3) imply that if the forward orbit of a point $(x,-2)$ is trapped, then the backward orbit of $(x,2)$ is also trapped.

A semi-plug is a manifold $P$ endowed with a vector field $\mathcal{X}$ as above, satisfying conditions (P1), (P3) and (P4), but not necessarily (P2). The concatenation of a semi-plug with an inverted copy of itself, that is a copy on any 3-manifold $M$ inside a flowbox, as follows. Let $\varphi: U_x \to (-1,1)^3$ be a coordinate chart which maps the vector field $\mathcal{X}$ on $M$ to the vertical vector field $\frac{\partial}{\partial z}$. Choose a modified embedding $i': P \to B(x, \epsilon) \subset (-1,1)^3$, and then replace the flow $\frac{\partial}{\partial z}$ in the interior of $i'(P)$ with the image of $\mathcal{X}$. This results in a flow $Z'$ on $M$.

The entry-exit condition implies that a periodic orbit of $Z$ which meets $\partial_h P$ in a non-trapped point, will remain periodic after this modification. An orbit of $Z$ which meets $\partial_h P$ in a trapped point never exits the plug $P$, hence after modification, limits to a closed invariant set contained in $P$. A closed invariant set contains a minimal set for the flow, and thus, a plug serves as a device to insert a minimal set into a flow.

We next introduce the "modified Wilson Plug", which is the first step in the construction of the Kuperberg Plug. Consider the rectangle

$$R = [1,3] \times [-2,2] = \{(r,z) \mid 1 \leq r \leq 3 \& -2 \leq z \leq 2\}.$$ 

Choose a $C^\infty$-function $g: R \to [0, g_0]$ for $g_0 > 0$, which satisfies the "vertical" symmetry condition $g(r, z) = g(r, -z)$. The value of $g_0 > 0$ is arbitrary; to be definite, we fix $g_0 = 1$ throughout this work. Also, require that $g(2, -1) = g(2, 1) = 0$, that $g(r, z) = 1$ for $(r, z)$ near the boundary of $R$, and that $g(r, z) > 0$ otherwise. Later, in [44], we will specify that $g(r, z) = 1$ for all points outside of an $\epsilon_0$-neighborhood of the vanishing points $(2, -1)$ and $(2, 1)$.
Define the vector field $W_v = g \cdot \frac{\partial}{\partial z}$ which has two singularities, $(2, \pm 1)$ and is otherwise everywhere vertical, as illustrated in Figure 1.

![Figure 1](image_url)

**Figure 1.** Vector field $W_v$

Next, choose a $C^\infty$-function $f: \mathbb{R} \to [-1,1]$ which satisfies the following conditions:

1. **(W1)** $f(r,-z) = -f(r, z)$ [anti-symmetry in $z$].
2. **(W2)** $f(\xi) = 0$ for $\xi$ near the boundary of $\mathbb{R}$.
3. **(W3)** $f(r, z) \geq 0$ for $-2 \leq z \leq 0$, and $f(r, z) > 0$ for $5/4 \leq r \leq 11/4$ and $-7/4 \leq z < 0$.
4. **(W4)** $f(r, z) \leq 0$ for $0 \leq z \leq 2$, and $f(r, z) < 0$ for $5/4 \leq r \leq 11/4$ and $0 < z \leq 7/4$.
5. **(W5)** $f(r, z) = 1$ for $5/4 \leq r \leq 11/4$ and $-7/4 \leq z \leq -1/4$.
6. **(W6)** $f(r, z) = -1$ for $5/4 \leq r \leq 11/4$ and $1/4 \leq z \leq 7/4$.

Condition (W1) implies that $f(r,0) = 0$ for all $1 \leq r \leq 3$, and that Conditions (W5) and (W6) are equivalent. Note that Conditions (W5) and (W6) are stated more precisely than in the works [27, 17, 34], as it is convenient to specify the values of $f$ on the specified domain in later considerations.

Next, define the manifold with boundary $W = [1,3] \times S^1 \times [-2,2] \cong \mathbb{R} \times S^1$ with cylindrical coordinates $x = (r, \theta, z)$. That is, $W$ is a solid cylinder with an open core removed, obtained by rotating the rectangle $R$, considered as embedded in $\mathbb{R}^3$, around the $z$-axis.

Extend the functions $f$ and $g$ above to $W$ by setting $f(r, \theta, z) = f(r, z)$ and $g(r, \theta, z) = g(r, z)$, so that they are invariant under rotations around the $z$-axis. The *modified Wilson vector field* $W$ on $W$ is defined by

$$W = g(r, \theta, z) \frac{\partial}{\partial z} + f(r, \theta, z) \frac{\partial}{\partial \theta}.$$  

Let $\Psi_t$ denote the flow of $W$ on $W$. Observe that the vector field $W$ is vertical near the boundary of $W$, and is horizontal for the points $(r, \theta, z) = (2, \theta, \pm 1)$. Also, $W$ is tangent to the cylinders $\{r = \text{const.}\}$. The flow $\Psi_t$ on the cylinders $\{r = \text{const.}\}$ is illustrated (in cylindrical coordinate slices) by Figures 2 and 3.

We give some of the basic properties of the Wilson flow. Let $R_\varphi: W \to W$ be rotation by the angle $\varphi$. That is, $R_\varphi(r, \theta, z) = (r, \theta + \varphi, z)$. Define the closed subsets:

| $C$   | {r = 2} | [The Full Cylinder] |
| $\mathcal{R}$ | $\{(2, \theta, z) \mid -1 \leq z \leq 1\}$ | [The Reeb Cylinder] |
| $\mathcal{A}$ | {z = 0} | [The Center Annulus] |
| $\mathcal{O}_i$ | $\{(2, \theta, (-1)^i)\}$ | [Periodic Orbits, $i=1,2$] |

Then $\mathcal{O}_1$ is the lower boundary circle of the Reeb cylinder $\mathcal{R}$, and $\mathcal{O}_2$ is the upper boundary circle.
PROPOSITION 2.1. Let $\Psi_t$ be the flow on $\mathcal{W}$ defined above, then:

1. $R_\varphi \circ \Psi_t = \Psi_t \circ R_\varphi$ for all $\varphi$ and $t$.
2. The flow $\Psi_t$ preserves the cylinders $\{r = \text{const.}\}$ and in particular preserves the cylinders $\mathcal{R}$ and $\mathcal{C}$.
3. $O_i$ for $i = 1, 2$ are the periodic orbits for $\Psi_t$.
4. For $x = (2, \theta, -2)$, the forward orbit $\Psi_t(x)$ for $t > 0$ is trapped.
5. For $x = (2, \theta, 2)$, the backward orbit $\Psi_t(x)$ for $t < 0$ is trapped.
6. For $x = (r, \theta, z)$ with $r \neq 2$, the orbit $\Psi_t(x)$ terminates in the top face $\partial^+_h \mathcal{W}$ for some $t \geq 0$, and terminates in $\partial^-_h \mathcal{W}$ for some $t \leq 0$.
7. The flow $\Psi_t$ satisfies the entry-exit condition (P2) for plugs.

Proof. The only assertion that needs a comment is the last, which follows by (W1) and the symmetry condition imposed on the functions $g$ and $f$. 

Observe that for the choice of $g_0 = 1$ for the maximum value of the function $g$, the typical orbit of $\mathcal{W}$ rises from $z = -2$ to $z = 2$ in less than one revolution around the circle parameter $\theta$. A smaller choice of $g_0$ much closer to 0 will result in a flow which climbs much slower, and so will possibly make many more revolutions before transiting the cylinder. This observation will be used in the discussion of the pseudogroup dynamics in Section 9 and also in the discussion of propellers in Sections 11 and 13.
3. The Kuperberg plug

The construction of the Kuperberg Plug begins with the modified Wilson Plug \( \mathbb{W} \) with vector field \( \mathbb{W} \). The first step is to re-embed the manifold \( \mathbb{W} \) in \( \mathbb{R}^3 \) as a *folded figure-eight*, as shown in Figure 4, preserving the vertical direction. A simple but basic point is that the embeddings of the faces of the plug are not “planar”.

![Figure 4. Embedding of Wilson Plug \( \mathbb{W} \) as a folded figure-eight](image)

The fundamental idea of the Kuperberg Plug is to construct two insertions of \( \mathbb{W} \) into itself, in such a way that the two periodic orbits will be trapped by these self-insertions. Moreover, the insertions are made so that the resulting space \( K \) is again embedded in \( \mathbb{R}^3 \). A key subtlety of the construction arises in the precise requirements on these self-insertions. As with the construction of the modified Wilson Plug, the description in the works [27, 17, 34] is qualitative, as this suffices to prove the aperiodicity of the resulting flow. As will be seen in later sections of this work, other properties of the dynamics of the flow \( \Phi_t \) in the resulting plug \( K \) are strongly influenced by the precise nature of these maps, so we specify the definitions and some properties of the insertion maps more carefully in this section. Later in the manuscript, we formulate additional “generic” requirements on the insertion maps, in order to obtain further properties about the dynamics of the flow \( \Phi_t \).

The construction begins with the choice in the annulus \([1, 3] \times S^1\) of two closed regions \( L_i \), for \( i = 1, 2 \), which are topological disks. Each region has boundary defined by two arcs: for \( i = 1, 2 \), \( \alpha_i' \) is the boundary contained in the interior of \([1, 3] \times S^1\) and \( \alpha_i \) in the outer boundary contained in the circle \( \{r = 3\} \), as depicted in Figure 5.

We fix these curves precisely. Let \( \zeta_1 = \pi/4 \) and \( \zeta_2 = -\pi/4 \), then define the arcs

\[
\alpha_1 = \{(3, \theta) \mid |\theta - \zeta_1| \leq 1/10\} \quad \text{and} \quad \alpha_2 = \{(3, \theta) \mid |\theta - \zeta_2| \leq 1/10\}.
\]

Let \( \alpha_i' \) be the curves in the interior of \( L_i \) in which the polar coordinates \((r, \theta)\) are parabolas with minimum values \( r = 3/2 \) and base the line segment \( \alpha_i \), as depicted in Figure 5. We choose an explicit form for the embedded curves, for example, given by \( \alpha_i' \equiv \{r = 3/2 + 300/2 \cdot (\theta - \xi_i)^2\} \).

Consider the closed sets \( D_i \equiv L_i \times [-2, 2] \subset \mathbb{W} \), for \( i = 1, 2 \). Note that each \( D_i \) is homeomorphic to a closed 3-ball, that \( D_1 \cap D_2 = \emptyset \) and each \( D_i \) intersects the cylinder \( \{r = 2\} \in \text{a rectangle} \). Label the top and bottom faces of these regions by

\[
L_i^\pm = L_i \times \{\pm 2\} \quad \text{and} \quad L_2^\pm = L_2 \times \{\pm 2\}.
\]

The next step is to define insertion maps \( \sigma_i : D_i \to \mathbb{W} \), for \( i = 1, 2 \), in such a way that the periodic orbits \( \mathcal{O}_i \) and \( \mathcal{O}_2 \) for the \( \Psi_{\text{f}} \)-flow intersect \( \sigma_i(L_i^-) \) in points corresponding to \( \mathbb{W} \)-trapped entry points for the modified Wilson Plug. Consider the two disjoint arcs \( \beta_i' \) in the inner boundary circle \( \{r = 1\} \),

\[
\beta_1' = \{(1, \theta) \mid |\theta - (\zeta_1 + \pi)| \leq 1/10\} \quad \beta_2' = \{(1, \theta) \mid |\theta - (\zeta_2 + \pi)| \leq 1/10\}.
\]
For $i = 1, 2$, choose orientation preserving diffeomorphisms $\sigma_i: \alpha'_i \to \beta'_i$, and extend these maps to smooth embeddings $\sigma_i: D_i \to \mathbb{W}$, as illustrated in Figure 6, which satisfy the conditions:

(K1) $\sigma_i(\alpha'_i \times z) = \beta'_i \times z$ for $z \in [-2, 2]$, and the interior arc $\alpha'_i$ is mapped to a boundary arc $\beta'_i$;

(K2) $D_i = \sigma_i(D_i) \subset \{(r, \theta, z) \mid 1 \leq r \leq 5/2, \ |\theta - (\zeta_i + \pi)| \leq 1/10\}$, thus $D_1 \cap D_2 = \emptyset$;

(K3) $\sigma_1(L^-_1) \cap \{r \geq 2\} \subset \{z < 0\}$ and $\sigma_2(L^-_2) \cap \{r \geq 2\} \subset \{z > 0\}$;

(K4) For every $x \in L_i$, the image $I_{i,x} \equiv \sigma_i(x \times [-2, 2])$ is an arc contained in a trajectory of $\mathbb{W}$;

(K5) Each slice $\sigma_i(L_i \times \{z\})$ is transverse to the vector field $\mathbb{W}$, for all $-2 \leq z \leq 2$;

(K6) $D_i$ intersects the periodic orbit $O_i$ and not $O_j$, for $i \neq j$.

The “horizontal faces” of the embedded regions $D_i = \sigma_i(D_i) \subset \mathbb{W}$ are labeled by

$$L_i^\pm = \sigma_1(L_i^\pm), \quad L_2^\pm = \sigma_2(L_2^\pm).$$

Note that the arcs $I_{i,x}$ in condition (K4) are line segments from $\sigma_i(x \times \{-2\})$ to $\sigma_i(x \times \{2\})$ which follow the $\mathbb{W}$-trajectory and traverse the insertion from the bottom face to the top face. Since $\mathbb{W}$ is vertical near
the boundary of $\mathcal{W}$, and horizontal in the two periodic orbits, we have that the arcs $L_{i,x}$ are vertical near the inserted curve $\sigma_i(x')$ and horizontal at the intersection of the insertion with the periodic orbit $O_i$. Thus, the embeddings of the surfaces $\sigma_i(L_i \times \{z\})$ make a half turn upon insertion, for each $-2 \leq z \leq 2$, as depicted in Figure 6. The turning is clockwise for the bottom insertion $i = 1$ as illustrated in Figure 6 and counter-clockwise for the upper insertion $i = 2$, which is not illustrated.

The image of the first insertion $\sigma_1(D_1)$ in Figure 6 intersects the first periodic orbit of $\mathcal{W}$ and is disjoint of the second periodic orbit. The image of the second insertion $\sigma_2(D_2)$ is disjoint from the first insertion and the first periodic orbit, and intersects the second periodic orbit.

The embeddings $\sigma_i$ are also required to satisfy two further conditions, which are the key to showing that the resulting Kuperberg flow $\Phi_t$ is aperiodic:

(K7) For $i = 1, 2$, the disk $L_i$ contains a point $(2, \theta_i)$ such that the image under $\sigma_i$ of the vertical segment $(2, \theta_i) \times [-2, 2] \subset D_i \subset \mathcal{W}$ is an arc $\{r = 2\} \cap \{\theta - \theta_i^+ \leq \theta \leq \theta_i^+ \} \cap \{z = (-1)^i\}$ of the periodic orbit $O_i$ of $\mathcal{W}$.

(K8) Radius Inequality. For all $x = (r, \theta, z) \in L_i \times [-2, 2]$, let $x' = (r', \theta', z') = \sigma_i(r, \theta, z) \in D_i$, then $r' < r$ unless $x = (2, \theta_i, z)$.

The Radius Inequality (K8) is one of the most fundamental concepts of Kuperberg’s construction. The condition (K4) and the fact that the flow of the vector field $\mathcal{W}$ on $\mathcal{W}$ preserves the radius coordinate on $\mathcal{W}$, allows restating (K8) in the more concise form for points in the faces $L_i^-$ of the insertion regions $D_i$. For $x' = (r', \theta', z') = \sigma_i(r, \theta, z) \in D_i$ we have

$$r(\sigma_i^{-1}(x')) \geq r'$$

for $x' \in L_i^-$, with $r(\sigma_i^{-1}(x')) = r'$ if and only if $x' = \sigma_i(2, \theta_i, -2)$.

The Radius Inequality (K8) is illustrated in Figure 7 below. This is an “idealized” case, as it implicitly assumes that the relation between the values of $r$ and $r'$ is “quadratic” in a neighborhood of the special points $(2, \theta_i)$, which is not required in order that (K8) be satisfied. Later in this work, this “quadratic condition” will be added as part of the generic hypotheses on the construction.

![Figure 7. The radius inequality illustrated](image)

The embeddings $\sigma_i : L_i \times [-2, 2] \to \mathcal{W}$, for $i = 1, 2$, can be constructed by first choosing smooth embeddings of the faces $\sigma_i : L_i^- \times \{-2\} \to \mathcal{W}$ so that the image surfaces are transverse to the vector field $\mathcal{W}$ on $\mathcal{W}$, and satisfy the conditions (K1), (K3), (K7) and (K8). Then we extend the embeddings of the faces $L_i^- \times \{-2\}$ to the cylinder sets $L_i \times [-2, 2]$ by flowing the images using a reparametrization of the flow of $\mathcal{W}$, so that we obtain embeddings of $L_i \times [-2, 2]$ satisfying conditions (K1) to (K8), and as pictured in Figure 6.

Finally, define $\mathcal{K}$ to be the quotient manifold obtained from $\mathcal{W}$ by identifying the sets $D_i$ with $D_i$. That is, for each point $x \in D_i$ identify $x$ with $\sigma_i(x) \in \mathcal{W}$, for $i = 1, 2$. This is illustrated in Figure 8.

The restricted $\Psi_t$-flow on the inserted disk $D_i = \sigma_i(D_i)$ is not compatible with the image of the restricted $\Psi_t$-flow on $D_i$. Thus, to obtain a smooth vector field $\mathcal{X}$ from this construction, it is necessary to modify $\mathcal{W}$ on each insertion $D_i$. The idea is to replace the vector field $\mathcal{W}$ on the interior of each region $D_i$ with the image
vector field, so that the dynamics of $\Phi_t$ in the interior of each insertion region $D_i$ reverts back to the Wilson dynamics on $D_i$. This requires a minor technical step first.

Smoothly reparametrize the image of $W|_{D_i}$ under $\sigma_i$ on an open neighborhood of the boundary of $D_i$ so that it agrees with the restriction of $W$ to the same neighborhood. This is possible since the vector field $W$ is vertical on a sufficiently small open neighborhood of the boundary of $D_i$ so is mapped by $\sigma_i$ to an orbit segment of $W$ by $(K4)$. We obtain a vector field $W'_i$ on $D_i$ with the same orbits as the image of $W|_{D_i}$. The case of $D_1$ is illustrated in Figure 6.

Then modify $W$ on each insertion $D_i$, replacing it with the modified image $W'_i$. Let $W'$ denote the vector field on $W$ after these modifications and note that $W'$ is smooth. By the modifications made above, the vector field $W'$ descends to a smooth vector field on $K$ denoted by $K$. Let $\Phi_t$ denote the flow of the vector field $K$ on $K$. The Kuperberg Plug is the resulting space, $K \subset \mathbb{R}^3$.

4. Transition points and the radius function

In this section, we introduce notations that will be used throughout this work and also some basic concepts which are fundamental for relating the dynamics of the two vector fields $W$ and $K$. These results are contained in the literature [17, 28, 27, 34], though in a variety of differing notations and presentations.

Recall that $D_i = \sigma_i(D_i)$ for $i = 1, 2$ are solid 3-disks embedded in $W$. Introduce the sets:

\[
W' \equiv W - \{D_1 \cup D_2\} \quad \text{and} \quad \hat{W} \equiv \overline{W - \{D_1 \cup D_2\}}.
\]

The closure $\hat{W}$ of $W'$ is the piège de Wilson creusé as defined in [17] page 292. The compact space $\hat{W} \subset W$ is the result of “drilling out” the interiors of $D_1$ and $D_2$, as the terminology creusé suggests.

For $x, y \in K$, we say that $x <_K y$ if there exists $t \geq 0$ such that $\Phi_t(x) = y$. Likewise, for $x', y' \in \hat{W}$, we say that $x' <_W y'$ if there exists $t \geq 0$ such that $\Psi_t(x') = y'$.

Let $\tau: \hat{W} \to K$ denote the quotient map, which for $i = 1, 2$, identifies a point $x \in D_i$ with its image $\sigma_i(x) \in D_i$. Then the restriction $\tau': \hat{W} \to K$ is injective and onto. Let $(\tau')^{-1}: K \to \hat{W}$ denote the inverse map, which followed by the inclusion $\hat{W} \subset W$, yields the (discontinuous) map $\tau^{-1}: K \to W$, where $i = 1, 2$, we have:

\[
\tau^{-1}(\tau(x)) = x \text{ for } x \in D_i, \text{ and } \sigma_i(\tau^{-1}(\tau(x))) = x \text{ for } x \in D_i.
\]
For \( x \in \mathbb{K} \), let \( x = (r, \theta, z) \) be defined as the \( \mathbb{W} \)-coordinates of \( \tau^{-1}(x) \subset \mathbb{W}' \). In this way, we obtain (discontinuous) coordinates \((r, \theta, z)\) on \( \mathbb{K} \). In particular, let \( r: \mathbb{W}' \to [1, 3] \) be the restriction of the radius coordinate on \( \mathbb{W} \), then the function is extended to the radius function of \( \mathbb{K} \), again denoted by \( r \), where for \( x \in \mathbb{K} \) set \( r(x) = r(\tau^{-1}(x)) \).

The flow of the vector field \( \mathbb{W} \) on \( \mathbb{W} \) preserves the radius function on \( \mathbb{W} \), so \( x' \prec_{\mathbb{W}} y' \) implies that \( r(x') = r(y') \). However, \( x \prec_{\mathbb{K}} y \) need not imply that \( r(x) = r(y) \). The points of discontinuity for the function \( t \mapsto r(\Phi_t(x)) \) play a fundamental role in the study of the dynamics of Kuperberg flows.

Let \( \partial_{\mathbb{w}}^+ \mathbb{K} \equiv \tau(\partial_{\mathbb{w}}^+ \mathbb{W} \setminus (L_1^- \cup L_2^-)) \) and \( \partial_{\mathbb{w}}^- \mathbb{K} \equiv \tau(\partial_{\mathbb{w}}^- \mathbb{W} \setminus (L_1^+ \cup L_2^+)) \) denote the bottom and top horizontal boundary components of \( \mathbb{K} \), respectively. Note that each of the surfaces \( \partial_{\mathbb{w}}^+ \mathbb{K} \) and \( \partial_{\mathbb{w}}^- \mathbb{K} \) is closed homeomorphic to a twice-punctured torus, as can be seen in Figure 9, and have boundary which is the union of two circles. By the choice of \( \mathbb{K} \), the vertical boundary components \( \partial_{\mathbb{w}}^\pm \mathbb{K} \equiv \tau(\mathbb{W} \cap \partial_{\mathbb{w}}^\pm \mathbb{W}) \) is tangent to \( \mathbb{K} \).

Points \( x' \in \partial_{\mathbb{w}}^- \mathbb{W} \) and \( y' \in \partial_{\mathbb{w}}^+ \mathbb{W} \) are said to be facing, and we write \( x' \equiv y' \), if \( x' = (r, \theta, -2) \) and \( y' = (r, \theta, 2) \) for some \( r \) and \( \theta \). The entry/exit property of the Wilson flow is then equivalent to the property that \( x' \equiv y' \) if \( [x', y']_{\mathbb{W}} \) is an orbit from \( \partial_{\mathbb{w}}^- \mathbb{W} \) to \( \partial_{\mathbb{w}}^+ \mathbb{W} \) whenever \( r(x') \neq 2 \). There is also a notion of facing points for \( x, y \in \mathbb{K} \), if either of two cases are satisfied:

- For \( x = \tau(x') \in \partial_{\mathbb{w}}^- \mathbb{K} \) and \( y = \tau(y') \in \partial_{\mathbb{w}}^+ \mathbb{K} \), if \( x' \equiv y' \) then \( x \equiv y \).
- For \( i = 1, 2 \), with \( x = \sigma_i(x') \) and \( y = \sigma_i(y') \), if \( x' \equiv y' \) then \( x \equiv y \).

The context in which the notation \( x \equiv y \) is used dictates which usage applies.

Consider the embedded disks \( L_i^\pm \subset \mathbb{W} \) defined by \( [5] \), which appear as the faces of the insertions in \( \mathbb{W} \). Their images in the quotient manifold \( \mathbb{K} \) are denoted by:

\[
E_i = \tau(L_i^-) \quad , \quad S_i = \tau(L_i^+) \quad , \quad E_2 = \tau(L_2^-) \quad , \quad S_2 = \tau(L_2^+) .
\]

Note that \( \tau^{-1}(E_i) = L_i^- \), while \( \tau^{-1}(S_i) = L_i^+ \). Also, introduce the notation:

\[
T_{\mathbb{K}} = E_1 \cup E_2 \cup S_1 \cup S_2 .
\]

Then by the formulation \( [9] \) of the Radius Inequality, the points of discontinuity along \( \mathbb{K} \)-orbits for the radius function \( r: \mathbb{K} \to [1, 3] \) are contained in the set \( T_{\mathbb{K}} \).

The set \( T_{\mathbb{K}} \subset \mathbb{K} \) is transverse to the flow \( \mathbb{K} \). The transition points of an orbit of \( \mathbb{K} \) are those points where the orbit intersects the transversal \( T_{\mathbb{K}} \), or terminate in a boundary component \( \partial_{\mathbb{w}}^- \mathbb{K} \) or \( \partial_{\mathbb{w}}^+ \mathbb{K} \). They are then either primary or secondary transition points, where \( x \in \mathbb{K} \) is:

- a primary entry point if \( x \in \partial_{\mathbb{w}}^- \mathbb{K} \);
- a primary exit point if \( x \in \partial_{\mathbb{w}}^+ \mathbb{K} \);
- a secondary entry point if \( x \in E_1 \cup E_2 \);
- a secondary exit point if \( x \in S_1 \cup S_2 \).

If a \( \mathbb{K} \)-orbit contains no transition points, then it lifts to a \( \mathbb{W} \)-orbit in \( \mathbb{W} \) flowing from \( \partial_{\mathbb{w}}^- \mathbb{W} \) to \( \partial_{\mathbb{w}}^+ \mathbb{W} \).

The special points for the flow \( \Phi_t \) are the images, for \( i = 1, 2 \),

\[
p^{-i}_i = \tau(O_i \cap L_i^-) \in E_i \quad , \quad p^+_{i-i} = \tau(O_i \cap L_i^+) \in S_i .
\]

Note that by definitions and the Radius Inequality, we have \( r(p^\pm_i) = 2 \) for \( i = 1, 2 \).

A \( \mathbb{W} \)-arc is a closed segment \( [x, y]_{\mathbb{K}} \subset \mathbb{K} \) of the flow of \( \mathbb{K} \) whose endpoints \( \{x, y\} \) lie in \( T_{\mathbb{K}} \), while the interior \( (x, y)_{\mathbb{K}} \) of the arc is disjoint from \( T_{\mathbb{K}} \). The open interval \( (x, y)_{\mathbb{K}} \) is then the image under \( \tau \) of a unique \( \mathbb{W} \)-orbit segment in \( \mathbb{W}' \), denoted by \( (x', y')_{\mathbb{W}} \) where \( \tau(x') = x \) and \( \tau(y') = y \) (see Figure \( [9] \)). Let \( [x', y']_{\mathbb{W}} \) denote the closure of \( (x', y')_{\mathbb{W}} \) in \( \mathbb{W} \), then we say that \( [x', y']_{\mathbb{W}} \) is the lift of \( [x, y]_{\mathbb{K}} \). Note that the radius function \( r \) is constant along \( [x', y']_{\mathbb{W}} \).

The properties of the Wilson flow \( \mathbb{W} \) on \( \mathbb{W} \) determine the endpoints of lifts \( [x', y']_{\mathbb{W}} \). We state the six cases which arise explicitly, as they will be cited in later arguments. Figure \( [9] \) helps in visualizing these cases.
LEMMA 4.1. Let \([x, y]_\mathcal{K} \subset \mathbb{K}\) be a \(\mathcal{W}\)-arc, and let \([x', y']_\mathcal{W} \subset \hat{\mathcal{W}}\) denote its lift.

(1) **(p-entry/entry)** If \(x\) is a primary entry point, then \(x' \in \partial^-_h \hat{\mathcal{W}} \setminus (L_1^- \cup L_2^-)\) and if \(y\) is a secondary entry point, we have \(y' \in \mathcal{L}_i^+\) for \(i = 1, 2\).

(2) **(p-entry/exit)** If \(x\) is a primary entry point, then \(x' \in \partial^-_h \hat{\mathcal{W}} \setminus (L_1^- \cup L_2^-)\) and if \(y\) is an exit point, then \(y' \in \partial^+_h \hat{\mathcal{W}}\) is a primary exit point, and by the entry/exit condition on \(\mathcal{W}\) we have \(x \equiv y\).

(3) **(s-entry/entry)** If \(x\) is a secondary entry point, then \(x' \in L_i^-\) for \(i = 1, 2\), and if \(y\) is an entry point, then we have \(y' \in \mathcal{L}_j^-\) where \(j = 1, 2\) is not necessarily equal to \(i\).

(4) **(s-entry/exit)** If \(x\) is a secondary entry point, then \(x' \in L_i^-\) for \(i = 1, 2\), and if \(y\) is an exit point, then \(y' \in L_i^+\) and \(x \equiv y\) by the entry/exit condition of \(\mathcal{W}\).

(5) **(s-exit/entry)** If \(x\) is a secondary exit point, then \(x' \in \mathcal{L}_i^+\) for \(i = 1, 2\), and if \(y\) is an entry point, so that \(y' \in \mathcal{L}_j^-\) then \(j = 2\) if \(i = 2\), and \(j = 1, 2\) if \(i = 1\).

(6) **(s-exit/exit)** If \(x\) is a secondary exit point, then \(x' \in \mathcal{L}_i^+\) for \(i = 1, 2\), and if \(y\) is a primary exit point, \(y' \in \partial^+_h \hat{\mathcal{W}} \setminus (L_1^+ \cup L_2^+)\). If \(y\) is a secondary exit point, then \(y' \in L_j^+\), where \(j = 1, 2\) is not necessarily equal to \(i\).

Figure 9 illustrates some of the notions discussed in this section. The disks \(L_1^-\) and \(L_2^-\) contained in \(\partial^-_h \hat{\mathcal{W}}\) are drawn in the bottom face, though they are partially obscured by the cylinder \(\{r = 1\}\). The image of \(L_1^-\) under \(\sigma_1\) is the entry face of the insertion region in the lower half of the cylinder, while the image of \(L_2^-\) under \(\sigma_2\) is the entry face of the insertion region in the upper half of the cylinder. Analogously, the disks \(L_1^+\) and \(L_2^+\) in \(\partial^+_h \hat{\mathcal{W}}\) are mapped to the exit region of the insertion regions. The intersection of the \(\mathcal{W}\)-periodic orbits \(\mathcal{O}_1\) and \(\mathcal{O}_2\) with \(\hat{\mathcal{W}}\) is illustrated, as well as two \(\mathcal{W}\)-arcs in \(\mathcal{W}'\) that belong to the same orbit. One \(\mathcal{W}\)-arc goes from \(\partial^-_h \hat{\mathcal{W}}\) to \(L_1^-\), hence from a principal entry point to a secondary entry point (as in Lemma 4.1(1)). The second \(\mathcal{W}\)-arc goes from \(\mathcal{L}_1^+\) to \(L_1^-\), thus from a secondary exit point to a secondary entry point (as in Lemma 4.1(5)).

Figure 9. \(\mathcal{W}\)-arcs lifted to \(\hat{\mathcal{W}}\)

Introduce the radius coordinate function along \(\mathcal{K}\)-orbits. For \(x \in \mathbb{K}\) set \(\rho_x(t) \equiv r(\Phi_t(x))\). Note that if \(\Phi_t(x) \not\in \mathcal{T}_\mathcal{K}\) then the function \(\rho_x(t)\) is locally constant at \(t\), and thus we have:

LEMMA 4.2. If the \(\mathcal{K}\)-arc \(\{\Phi_t(x) \mid t_0 \leq t \leq t_1\}\) contains no transition point, then \(\rho_x(t) = \rho_x(t_0)\) for all \(t_0 \leq t \leq t_1\).
The level function along an orbit indexes the discontinuities of the radius function. Given \( x \in \mathbb{K} \), set \( n_x(0) = 0 \) and for \( t > 0 \) define

\[
n_x(t) = \# \{(E_1 \cup E_2) \cap \Phi_s(x) \mid 0 < s \leq t\} - \# \{(S_1 \cup S_2) \cap \Phi_s(x) \mid 0 < s \leq t\}.
\]

That is, \( n_x(t) \) is the total number of secondary entry points, minus the total number of secondary exit points, traversed by the flow of \( x \) over the interval \( 0 < s \leq t \). For example, suppose that \( x_1 = \Phi_s(x) \) is the first transition point for \( t > 0 \). If \( x_1 \) is a secondary entry point, then \( n_x(t_1) = 1 \), while \( n_x(t_1) = -1 \) if \( x_1 \) is a secondary exit point. Thereafter, \( n_x(t) \) changes value by \( \pm 1 \) at each \( t > t_1 \) such that \( \Phi(x) \in \mathcal{T}_K \) and whether the value increases or decreases, indicates whether the transition point is an entry or exit point.

The function can be extended to negative time by setting, for \( t < 0 \),

\[
n_x(t) = \# \{(S_1 \cup S_2) \cap \Phi_s(x) \mid t < s \leq 0\} - \# \{(E_1 \cup E_2) \cap \Phi_s(x) \mid t < s \leq 0\}.
\]

Endow the manifold \( \mathbb{K} \) with a Riemannian metric, induced from the natural coordinates on \( \hat{\mathbb{W}} \). Along the boundaries \( \partial_h \hat{\mathbb{W}} \) it is necessary to make a small adjustment to the Riemannian metric so that it becomes smooth on the quotient space \( \mathbb{K} \). We can assume that the vector field \( \mathcal{K} \) on \( \mathbb{K} \) has unit length, and so the adjustments are made to the metric transverse to \( \mathcal{K} \) in a small open neighborhood of these boundaries. Let \( d_{\mathcal{K}} \) denote the resulting path length metric on \( \mathbb{K} \).

Let \( d_{\mathbb{W}} \) be the path length metric in \( \mathbb{W} \). By the assumption that \( \mathcal{K} \) is unit length, the metric \( d_{\mathbb{W}} \) is just the same as that derived from the time coordinate along the flow \( \Phi_t \). For example, by this convention, the length of the circles \( \{(r, \theta, 0) \mid 0 \leq \theta \leq 2\pi\} \subset \mathbb{K} \) is \( 2\pi \).

For \( x' \prec_{\mathbb{W}} y' \) in \( \mathbb{W} \), let \( d_{\mathbb{W}}(x', y') \) denote the path length of the \( \mathbb{W} \)-orbit segment \([x', y']_{\mathbb{W}}\) between them. Similarly, for \( x \prec_{\mathcal{K}} y \) in \( \mathbb{K} \), let \( d_{\mathcal{K}}(x, y) \) denote the path length of the \( \mathcal{K} \)-orbit segment \([x, y]_{\mathcal{K}}\). Note that if \( [x, y]_{\mathcal{K}} \) is a \( \mathcal{W} \)-arc with lift \([x', y']_{\mathbb{W}}\), then \( d_{\mathcal{K}}(x, y) = d_{\mathbb{W}}(x', y') \).

We establish some basic length estimates which are used in later sections.

**Lemma 4.3.** There exists \( 0 < \epsilon < 1 \) such that for any \( \xi \in \mathbb{W} \) with \( |r(\xi) - 2| \geq \epsilon \), the total \( \mathbb{W} \)-orbit segment \([x', y']_{\mathbb{W}}\) through \( \xi \) has length bounded above by \( L(\epsilon) \).

**Proof.** Since \( r(\xi) \neq 2 \), the orbit of \( \mathbb{W} \) containing \( \xi \) is finite, hence there exists \( x'_\xi \in \partial_h \hat{\mathbb{W}} \) such that \( x'_\xi = \Phi_s(\xi) \) for some \( t \leq 0 \). Likewise, there exists \( s \geq 0 \) such that \( y'_\xi = \Phi_s(\xi) \in \partial_h \hat{\mathbb{W}} \). Then \([x'_\xi, y'_\xi]_{\mathbb{W}}\) is the complete \( \mathbb{W} \)-orbit containing \( \xi \). In particular, \( d_{\mathbb{W}}(x'_\xi, y'_\xi) < \infty \).

The function \( \xi \mapsto d_{\mathbb{W}}(x'_\xi, y'_\xi) \) is continuous on the open domain \( r(\xi) \neq 2 \). Since the flow in \( \mathbb{W} \) is rotationally invariant, this function depends only on \( r(\xi) \). Let \( L(\epsilon) \) denote the maximum of this length function on the compact domain \( |r(\xi) - 2| \geq \epsilon \). \( \square \)

**Lemma 4.4.** There exists \( 0 < d_{\min} < d_{\max} \) such that if \([x', y']_{\mathbb{W}} \subset \hat{\mathbb{W}} \) is the lift of a \( \mathbb{W} \)-arc \([x, y]_{\mathcal{K}}\), then we have the uniform estimate

\[
d_{\min} \leq d_{\mathbb{W}}(x', y') \leq d_{\max}.
\]

**Proof.** First, suppose that \( x' \in \partial_h \hat{\mathbb{W}} \) and so either \( y' \in \mathcal{L}_i^- \) for \( i = 1, 2 \) or \( y' \in \partial_h \hat{\mathbb{W}} \). The set of points \( x' \in \partial_h \hat{\mathbb{W}} \) whose forward orbit has first transition point in \( \mathcal{L}_i^- \) is a compact set containing the circle \( \{(2, \theta, -2) \mid 0 \leq \theta \leq 2\pi\} \subset \mathbb{W} \) in its interior. Thus, there is a lower and upper bound for the length \( d_{\mathbb{W}}(x', y') \).

Away from the core circle in \( \partial_h \hat{\mathbb{W}} \), the \( \mathbb{W} \)-orbit for a point \( x' \in \partial_h \hat{\mathbb{W}} \) with \( r(x') \neq 2 \) is not trapped, so terminates in \( y' \in \partial_h \hat{\mathbb{W}} \). Moreover, the set of \( x' \) whose \( \mathbb{W} \)-orbit does not intersect the compact set \( \mathcal{L}_i^- \) has \( r(x') \) value bounded away from 2 by the previous case, and thus there exists \( \epsilon > 0 \) so \( |r(x') - 2| \geq \epsilon \). Then by Lemma 4.3, the length \( d_{\mathbb{W}}(x', y') \) is then bounded above by \( L(\epsilon) \). The lower bound on \( d_{\mathbb{W}}(x', y') \) follows from the compactness of the set \( \{x' \in \partial_h \hat{\mathbb{W}} \mid |r(x') - 2| \geq \epsilon \} \).

The analysis of the cases where \( x' \in \mathcal{L}_i^+ \), for \( i = 1, 2 \), proceeds similarly. \( \square \)
COROLLARY 4.5. Let \([x,y]_K \subset K\) be a \(W\)-arc. Then there is a uniform length estimate
\[
d_{\min} \leq d_K(x,y) \leq d_{\max}.
\]

These results then combine to give the observation:

COROLLARY 4.6. The Wilson orbit through \(x' \in W\) with \(r(x') \neq 2\) contains at most a finite number of lifts of distinct \(W\)-arcs, partially-ordered by the relation \(\prec_W\).

We summarize the dynamical properties of orbits for \(\Phi_t\) which follow from the above results.

For each \(x \in K\) the \(K\)-orbit \(\{\Phi_t(x) \mid a \leq t \leq b\}\), where \(-\infty \leq a < b \leq \infty\), can be decomposed in a finite or infinite family of \(W\)-arcs \(\{[x'_i, y'_{i+1}]_W\} \subset W\). These \(W\)-arcs are indexed relative to the initial point \(x\) by the level function \(n_x(t)\) and the radius function \(\rho_x(t)\), both functions are constant along \((x_i, y_{i+1})_K\). Thus, the \(W\)-arcs can be grouped according to the values \(\rho_x(t)\) and so grouped, lie in orbits of the Wilson flow in disjoint cylinders \(\{r = \text{const.}\}\).

The \(K\)-orbit of \(x\) is then determined by understanding when two segments \([x'_i, y'_{i+1}]_W\) and \([x'_j, y'_{j+1}]_W\) have the same \(r\)-value and so lie in a common cylinder. Then whether they are contained in a common \(W\)-orbit within that cylinder, so that \(x'_i \prec_W x'_j\) or \(x'_j \prec_W x'_i\). By Corollary 4.6 there can be only a finite number of segments in each finite \(W\)-orbit.

Once the arcs have been grouped according to their \(\text{"}W\text{-orbit type\"}\), it then remains to understand how these \(W\)-arcs are assembled to give the full \(K\)-orbit, while satisfying the constraints imposed by the Radius Inequality (K8).

5. Semi-local dynamics

In this section, we establish a variety of properties of the level function and how it relates the dynamical behavior of the Wilson flow \(\Psi\), with the much more complicated dynamical behavior of the Kuperberg flow \(\Phi_t\). This relationship is one of the main themes in the understanding of the dynamics of the flow \(\Phi_t\), as developed in this work.

We first consider the properties of finite length segments of \(K\)-orbits. The results presented below are formulations, in our notation, of results which are contained in the works [17, 28, 27, 34] and are the most basic techniques used in the analysis of the dynamics of the Kuperberg flow.

We say that the \(K\)-orbit of \(x \in K\) is trapped in forward time if the forward orbit is defined for all \(t \geq 0\), so that the segment \(\{\Phi_t(x) \mid t \geq 0\} \subset K\). In particular, this forward orbit never intersects \(\partial^+ K\). Likewise, the \(K\)-orbit of \(x \in K\) is trapped in backward time if the segment \(\{\Phi_t(x) \mid t \leq 0\} \subset K\). When it is clear whether forward or backward time is meant, such as for points on the faces \(\partial^\pm K\), we simply refer to a trapped orbit.

The \(K\)-orbit of \(x\) is infinite if it is trapped in both forward and backward time.

For a \(K\)-orbit segment \([x, y]_K\), we define its “lift” to \(\hat{W}\), which is a union of lifts of \(W\)-orbit segments. This is a fundamental technical construction and introduces another useful notational convention. Let \(0 \leq t_0 < t_1 < \cdots < t_n\) be such that \(x_{t_i} = \Phi_{t_i}(x)\) are the successive transition points in \([x, y]_K\) so that
\[
[x, y]_K = [x, x_0]_K \cup [x_0, x_1]_K \cup \cdots \cup [x_{t_i}, x_{t_{i+1}}]_K \cup \cdots \cup [x_n, y]_K \subset K.
\]
By convention, \([x, x_0]_K\) is defined to be empty if \(x = x_0\), and otherwise has a well-defined lift \([x', y'_0]_W \subset \hat{W}\). The case for \(y\) is analogous. Each \(W\)-arc \([x_{t_i}, x_{t_{i+1}}]_K\) for \(0 \leq t < n\) lifts to a \(W\)-orbit segment \([x'_{t_i}, y'_{t_{i+1}}]_W \subset \hat{W}\), where \(\tau(x'_{t_{i+1}}) = \tau(y'_{t_{i+1}}) = x_{t_{i+1}}\) though \(y'_{t+1} \neq x'_{t+1}\). The lift of \([x, y]_K\) to \(\hat{W}\) is defined to be the collection of orbit segments in \(\hat{W}\),
\[
\{[x', y'_0]_W, [x'_0, y'_1]_W, \cdots, [x'_{t_i}, y'_{t_{i+1}}]_W, \cdots, [x'_{t_n-1}, y'_n]_W, [x'_n, y']_W\}.
\]
The lift of a \(K\)-orbit segment is closely related to the behavior of the level function \(n_x(t)\) along an orbit. Given a \(K\)-orbit segment \([x_0, x_n]_K\), where \(x_0 = \Phi_0(x)\), decompose it into \(W\)-arcs as in (16). The orbit \(\Phi_t(x)\) for \(t > 0\)
flows from \( x \) until it hits a transition point \( x_1 \). This initial \( \mathcal{W} \)-arc \([x_0, x_1]_\mathcal{K}\) is the image under \( \tau \) of a \( \mathcal{W} \)-orbit segment \([x_0', y_1']_\mathcal{W} \subset \hat{\mathcal{W}}\) as in \([17]\). After this first transition point, it then follows the image of the vector field \( \mathcal{W} \) under an insertion map \( \sigma_i \), which is again the image of a \( \mathcal{W} \)-orbit segment \([x_1', y_2']_\mathcal{W} \subset \hat{\mathcal{W}}\). At the next transition point, the flow \( \Phi_t(x) \) either exits the insertion and reverts back to the same orbit of \( \mathcal{W} \) in \( \hat{\mathcal{W}} \); or, it flows into another insertion, and thus the orbit is the image of a \( \mathcal{W} \)-arc into an insertion within the first insertion. This process continues along the entire \( \mathcal{K} \)-orbit segment. The level function \( n_\tau(t) \) counts the number of such insertions within insertions along the \( \mathcal{K} \)-segment \([x_0, x_n]_\mathcal{K}\), so measures the “depth of penetration” of the orbit into the self-insertion process used to construct the plug \( \mathcal{K}\).

![Figure 10. Decomposition into \( \mathcal{W} \)-arcs in the cylinders \( \{r = 2\} \subset \hat{\mathcal{W}} \)](image)

We illustrate this orbit decomposition in Figure 10 that represents the cylinder \( \{r = 2\} \) in \( \hat{\mathcal{W}} \). Consider the first periodic orbit and its intersection with \( \hat{\mathcal{W}} \), which is pictured as the lower horizontal line in the drawing. Flowing in forward time, the lift of the \( \mathcal{K} \)-orbit first intersects the entry face \( \mathcal{L}^-_1 \) of the lower insertion in a “special point”. The flow then continues to a point in the lower boundary of the same cylinder \( \{r = 2\} \) where it enters. Thus the next \( \mathcal{W} \)-arc in this orbit is in the same cylinder. It starts climbing and turning, until it hits the first insertion and exits the cylinder \( \{r = 2\} \) through \( \mathcal{L}^-_1 \). We prove, in Proposition 6.7, that after a certain time this orbit comes back to the cylinder \( \{r = 2\} \) in the facing point. Thus the \( \mathcal{K} \)-orbit will eventually pass the insertion and continue in the same \( \mathcal{W} \)-orbit for another turn before hitting the insertion again. This pattern then repeats infinitely many times. Flowing in backward time, the lift of the \( \mathcal{K} \)-orbit containing the arc \( \mathcal{O}_1 \cap \hat{\mathcal{W}} \), first intersects the exit face \( \mathcal{L}^+_2 \) in a special point. The orbit then continues to a point in the upper bound of the cylinder. It thus descends turning until it hits the exit face \( \mathcal{L}^+_2 \). Proposition 6.7 applies, implying that after a certain time this backward orbit comes back to the cylinder and continues descending and turning. This process repeats infinitely many times. Remark that the \( \mathcal{K} \)-orbit containing the arc \( \mathcal{O}_1 \cap \hat{\mathcal{W}} \) accumulates in forward time on \( \mathcal{O}_2 \cap \hat{\mathcal{W}} \) and in backward time on \( \mathcal{O}_2 \cap \hat{\mathcal{W}} \). Applying the same analysis to the \( \mathcal{K} \)-orbit containing \( \mathcal{O}_2 \cap \hat{\mathcal{W}} \), we obtain the same conclusion. This argument is explained again in the proof of Proposition 7.1.

We next give a sequence of technical results concerning the properties of the lift \((17)\) of a path as in \([16]\), beginning with the very simple concept of a short-cut, which was introduced in \([27]\), and developed in more detail in \([17]\, [28]\, [34]\).

**Lemma 5.1** (Short-cut). Suppose that \( x \in \mathcal{E}_i \) and \( y \in \mathcal{S}_i \) are facing. Then there exists \( x', y' \in \hat{\mathcal{W}} \) such that \( \tau(x') = x, \tau(y') = y \) and \( x' \prec_\mathcal{W} y' \). That is, there is a \( \mathcal{W} \)-orbit segment \([x', y']_\mathcal{W} \subset \hat{\mathcal{W}} \) (the short-cut) between \( x' \) and \( y' \).

**Proof.** Let \( x' \in \mathcal{L}^-_1 \) with \( \tau(x') = x \) and \( y' \in \mathcal{L}^+_1 \) with \( \tau(y') = y \). Consider \( x'' \in \mathcal{L}^-_1 \) with \( \sigma_i(x'') = x' \) and \( y'' \in \mathcal{L}^+_1 \) with \( \sigma_i(y'') = y' \). Then \( x \equiv y \) implies \( x'' \equiv y'' \) by definition. By (K4) the image \( \sigma_i(\mathcal{I}_{x',x''}) \) is a \( \mathcal{W} \)-orbit segment in \( \mathcal{D}_i \) with endpoints \( x', y' \). Thus, \( x' \prec_\mathcal{W} y' \). \( \square \)
Note that the short-cut path $[x', y']_W \subset \widehat{W}$ has endpoints in $\mathcal{L}_1^\pm$ and “bridges the gap” between these two faces in $\widehat{W}$. In Figure 9, this may be viewed as filling in with a flow line across any of the insertion boxes, from an entry point to an exit point.

Note that for a short-cut, the length of the path segment $[x', y']_W$ is bounded above by Lemma 4.4, independent of the choice of the points $x, y$. On the other hand if we are only given that $x <_\mathbb{K} y$, then no such a priori bound exists. Thus, the $\mathcal{W}$-path $[x', y']_W$ is truly a “short-cut” between $x'$ and $y'$ when compared to the length of the $\mathcal{K}$-path between $x$ and $y$.

The next result shows that given a pair of $\mathcal{W}$-arcs in $\mathbb{K}$ whose inner endpoints are facing, there is a $\mathcal{W}$-orbit segment in $\widehat{W}$ containing the lifts of both $\mathcal{W}$-arcs.

**Lemma 5.2.** Let $x, y, z, u \in \mathbb{K}$ be successive transition points on a $\mathcal{K}$-orbit, such that $x' \prec_w y', z' \prec_w u'$, $y$ is an entry point, $z$ is an exit point and $y \equiv z$. Then $x' \prec_w u'$ and hence $r(x') = r(u')$.

**Proof.** Observe that $x' \prec_w y'$ implies $y$ must be a secondary entry point, thus by Lemma 4.1 the endpoint $y'$ of the $\mathcal{W}$-orbit segment $[x', y']_W$ must lie in $\mathcal{L}_i^-$ for some $i = 1, 2$. Similarly, $z$ must be a secondary exit point, thus the endpoint $z'$ of the $\mathcal{W}$-orbit segment $[z', u']_W$ must lie in $\mathcal{L}_j^+$ for some $j$. The assumption $y \equiv z$ implies that $i = j$. Then by Lemma 5.1 there is a $\mathcal{W}$-arc in $\widehat{W}$ between $y'$ and $z'$, a short-cut. Thus, $y' \prec_w z'$, and so $x' \prec_w y' \prec_w z' \prec_w u'$ which implies $x' \prec_w u'$ and so $r(x') = r(u')$. □

The following result gives a criteria for when a pair of $\mathcal{W}$-arcs, whose inner endpoints lift to points which can be joined by a $\mathcal{W}$-orbit segment in $\widehat{W}$, are themselves contained in a $\mathcal{W}$-orbit segment and have facing endpoints.

**Lemma 5.3.** Suppose that $x \in \mathbb{K}$ is an entry point, $u \in \mathbb{K}$ is an exit point, $[x, y]_\mathbb{K}$ and $[u, z]_\mathbb{K}$ are $\mathcal{W}$-arcs with lifts $[x', y']_W$ and $[z', u']_W$. If $y' \prec_w z'$, then $x' \prec_w u'$ and $x \equiv u$.

**Proof.** Let $[x', y']_W \subset \widehat{W}$ be the lift of $[x, y]_\mathbb{K}$. The fact that $x$ is an entry point implies that $x' \in \partial_-^+ \widehat{W}$ and so either $y' \in \mathcal{L}_i^-$ for $i = 1, 2$, or $y' \in \partial_-^+ \widehat{W}$. The assumption that $y' \prec_w z'$ implies there is a $\mathcal{W}$-orbit segment from $y'$ to $z'$ so the case $y' \in \partial_-^+ \widehat{W}$ is impossible. Similarly, let $[z', u']_W \subset \widehat{W}$ be the lift of $[u, z]_\mathbb{K}$, then $u$ is an exit point implies that $u' \in \partial_-^+ \widehat{W}$ and so $z' \in \mathcal{L}_j^-$ for $j = 1, 2$ as $y' \prec_w z'$ is given. Thus, concatenating the $\mathcal{W}$-orbits segments from $x'$ to $y'$ to $z'$ to $u'$ yields $x' \prec_w u'$. The entry/exit property for the Wilson flow on $\widehat{W}$ implies that $x'$ and $u'$ are facing, hence $x \equiv u$. □

The next result gives a criteria using the level function, for when a sequence of three $\mathcal{K}$-arcs admit a lift to a segment of the $\Psi_r$-flow.

**Lemma 5.4.** [34] Corollary 4.2 Let $x \in \mathbb{K}$. Given successive transition points $x_t = \Phi_t(x)$ where $0 = t_0 < t_1 < t_2 < t_3$, suppose that $n_{x_0}(t) \geq 0$ for all $0 \leq t < t_3$, and that $n_{x_0}(t_2) = 0$. Then $x_1 \equiv x_2, x'_0 \prec_w y'_3$ and hence $r(x'_0) = r(y'_3)$.

**Proof.** For $0 \leq \ell < 3$, let $[x'_\ell, y'_{\ell+1}]_W \subset \widehat{W}$ be the lift of the $\mathcal{W}$-arc $[x_\ell, x_{\ell+1}]_\mathbb{K}$. The fact that $n_{x_0}(t_0) = 0$ and the assumption $n_{x_0}(t_1) \geq 0$ implies that $n_{x_0}(t_1) = 1$. Then $x_1$ is a secondary entry point, with $y'_1 \in \mathcal{L}_i^-$ for $i = 1$ or $i = 2$. Similarly, the assumption $n_{x_0}(t_2) = 0$ implies that $x_2$ is a secondary exit point, with $x'_2 \in \mathcal{L}_j^+$ for $j = 1$ or $j = 2$.

For the middle $\mathcal{W}$-arc $[x'_1, y'_2]_W \subset \widehat{W}$, we must then have $x'_1 \in L_i^-$ and $y'_2 \in L_j^+$. By the entry/exit assumption on $\widehat{W}$, we have $x'_1 \equiv y'_2$ so that $i = j$ and $x_1 \equiv x_2$. It follows that there exist a short-cut $[y'_1, x'_2]_W \subset D_i$ between $y'_1$ and $x'_2$. Thus we have $x'_0 \prec_w y'_3$.

In geometric terms, the lifts of the $\mathcal{W}$-arcs in Lemma 5.4 to $\widehat{W}$ do not form a continuous $\mathcal{W}$-orbit segment, due to the discontinuity of the map $\tau$, but by replacing the middle segment $[x'_1, y'_2]_W$ with a short-cut $[y'_1, x'_2]_W$ through $D_i$ we obtain a $\mathcal{W}$-orbit segment $[x'_0, y'_3]_W$. This is illustrated in Figure 11.
Next, we use Lemmas 5.1 to 5.4 to obtain a general form of Lemma 5.4, which is one of the fundamental results concerning the finite orbits of the Kuperberg flow.

**PROPOSITION 5.5.** [17] Let \( x \in \mathcal{K} \). For \( n \geq 3 \), assume there are given successive transition points \( x_\ell = \Phi_{t_\ell}(x) \) for \( 0 = t_0 < t_1 < \cdots < t_{n-1} < t_n \). Suppose that \( n_{x_\ell}(t) \geq 0 \) for all \( 0 \leq t < t_n \) and that \( n_{x_\ell}(t_{n-1}) = 0 \). Then \( x_0' \prec_W y'_n \), and hence \( r(x_0') = r(y'_n) \). Moreover, if \( x_0 \) is an entry point and \( x_n \) is an exit point, then \( x_0 \equiv x_n \).

**Proof.** For \( 0 \leq \ell < n \), let \( [x_\ell, y_{\ell+1}]_\mathcal{W} \subset \hat{\mathcal{W}} \) be the lift of the \( \mathcal{W} \)-arc \( [x_\ell, y_{\ell+1}]_\mathcal{K} \). The fact that \( n_{x_\ell}(t_0) = 0 \) and the assumption \( n_{x_\ell}(t_1) \geq 0 \) implies that \( n_{x_\ell}(t_1) = 1 \). Then \( x_1 \) is a secondary entry point, with \( y'_1 \in \mathcal{L}^-_1 \) for \( i = 1 \) or \( i = 2 \). Similarly, the assumption \( n_{x_\ell}(t_{n-1}) = 0 \) and \( n_{x_\ell}(t_{n-2}) \geq 0 \) implies that \( x_{n-1} \) is an exit point. Then \( x_{n-1} \) must be a secondary exit point and thus \( x'_{n-1} \in \mathcal{L}^+_j \) for \( j = 1 \) or \( j = 2 \). The case \( n = 3 \) then follows from Lemmas 5.3 and 5.4.

For the case \( n > 3 \), we proceed by induction. Assume that the result holds for all \( \mathcal{K} \)-segments containing at most \( n \) transition points. We will now prove the result for a segment with \( n + 1 \) transition points \( x_\ell \) for \( 0 \leq \ell \leq n \). Observe that by hypothesis, \( n_{x_\ell}(t_1) = n_{x_\ell}(t_{n-2}) \). If there exists \( 3 \leq \ell \leq n - 2 \) such that \( n_{x_\ell}(t_{\ell-1}) = 0 \), then consider the least such \( \ell \). By the inductive hypothesis, we have that \( x_0' \prec_W y'_n \), and as \( n_{x_\ell}(t_{\ell-1}) = 0 \), we also have that \( x'_{\ell-1} \prec_W y'_n \). Both \( \mathcal{W} \)-segments contain the arc \( [x'_{\ell-1}, y'_\ell]_\mathcal{W} \subset \hat{\mathcal{W}} \). Thus, the last arc of the \( \mathcal{W} \)-orbit segment \( [x_0', y'_\ell]_\mathcal{W} \) and the first arc of the \( \mathcal{W} \)-orbit segment \( [x'_{\ell-1}, y'_\ell]_\mathcal{W} \) must agree, hence \( x_0' \prec_W y'_n \) as claimed.

If in addition, \( x_0 \) is an entry point and \( x_n \) is an exit point, then \( x_0' \prec_W y'_n \) implies \( x_0 \equiv x_n \) by Lemma 5.3.

If \( n_{x_\ell}(t) \geq 1 \) for all \( t_1 \leq t < t_{n-1} \), then apply the inductive hypothesis to the segment \( [x_1, x_{n-1}]_\mathcal{K} \) to obtain \( x'_1 \prec_W y'_{n-1} \). Using the induction, we have that since \( x_1 \) is an entry point and \( x_{n-1} \) is an exit point, hence \( x_1 \equiv x_{n-1} \). Then, Lemma 5.2 implies that \( x'_0 \prec_W y'_n \leq r(x'_0) = r(y'_n) \). If in addition, \( x_0 \) is an entry point and \( x_n \) is an exit point, then again, \( x'_0 \prec_W y'_n \) implies that \( x_0 \equiv x_n \).

Proposition 5.5 implies that the flow \( \Phi_t \) on \( \mathcal{K} \) satisfies the entry/exit condition.

**PROPOSITION 5.6.** [31] Proposition 5.2] Let \( x \in \partial^+ \mathcal{K} \) be a primary entry point and suppose \( x_\ell = \Phi_{t_\ell}(x) \) for \( 0 = t_0 < t_1 < \cdots < t_{n-1} < t_n \) are successive transition points. If \( y = x_n \) is a primary exit point, then \( x \prec_W y \) and hence \( x \equiv y \). Moreover, \( n_x(t) \geq 0 \) for \( 0 \leq t < t_n \).

**Proof.** If \( n = 1 \), then \( [x_0, x_1]_\mathcal{K} \) is a \( \mathcal{W} \)-arc, and the conclusion follows by the entry/exit condition for \( \mathcal{W} \). The case \( n = 2 \) is impossible by Lemma 4.4.

If \( n = 3 \), note that \( x_1 \) must be a secondary entry point, hence \( n_x(t_1) = 1 \). The case \( n_x(t_2) = 2 \) is impossible, as \( x_2 \) is a primary exit point, hence \( x_2 \) must be a secondary exit point, contrary to assumption. Thus \( n_x(t_2) = 0 \). Then by Lemma 5.4 we have \( x'_1 = y'_2 \) and \( x'_0 \prec_W y'_3 \). As \( x'_0 \) is a primary entry point, and \( y'_3 \) is a primary exit point of \( \mathcal{W} \), they must be facing, or \( x \equiv y \).
Now assume that \( n > 3 \). As before, \( x_1 \) must be a secondary entry point with \( n_x(t_1) = 1 \), so it suffices to prove that \( n_x(t_{n-1}) = 0 \) and \( n_x(t) \geq 0 \) for all \( 0 \leq t \leq t_{n-1} \), and then apply Proposition 5.5. This will imply that \( x'_0 \prec_W y'_n \) and as \( x_0 = x \) is a primary entry point and \( x_n = y \) is a primary exit point, then \( x \equiv y \).

We claim that \( n_x(t) \geq 0 \) for all \( 0 \leq t < t_n \). Suppose not, then there exists a least \( 2 < \ell < n \) such that \( n_x(t_{\ell}) = -1 \). Then \( n_x(t) \geq 0 \) for all \( 0 \leq t < t_\ell \) and \( n_x(t_{\ell-1}) = 0 \). By Proposition 5.5 we have \( x'_0 \prec_W y'_\ell \), and since \( x_\ell \) is an exit point, we have \( x_\ell \equiv x_n \). This implies that \( x_\ell \) is a primary exit point, which is a contradiction as \( \ell < n \). We can thus consider that \( n_x(t) \geq 0 \) for all \( t_0 \leq t \leq t_n \) and that \( n_x(t_1) = 1 \).

If \( n_x(t_{n-1}) = k > 0 \), then the greatest integer \( 0 < \ell < n \) such that \( n_x(t_\ell) = k \) and \( n_x(t_{\ell-1}) = k - 1 \). Then the \( \mathcal{K} \)-orbit segment \([x_\ell, x_n]_\mathcal{K}\) satisfies the conditions of Proposition 5.5 with \( x_\ell \) an entry point, so that \( x'_\ell \prec_W y'_n \) and \( x_\ell \equiv x_n \). As \( x_n \) is a primary exit point and \( x_\ell \equiv x_n \), the entry/exit property of the Wilson flow implies that \( x_\ell \) is a primary entry point. This is a contradiction as we have that \( t_\ell > 0 \). Then \( n_x(t_{n-1}) = 0 \) and the proof is finished. \( \square \)

In summary, the proofs of Propositions 5.5 and 5.6 show that, given a \( \mathcal{K} \)-orbit segment \([x, y]_\mathcal{K}\) in \( \mathcal{K} \) with \( x \) an entry point, \( y \) a facing exit point, the condition \( n_x(t) \geq 0 \) for the \( \mathcal{K} \)-orbit between the two points, then there exists a \( \mathcal{W} \)-orbit segment \([x'_0, y'_n]_\mathcal{W}\) in \( \mathcal{W} \) between lifts \( x'_0 \) of \( x \) and \( y'_n \) of \( y \). The \( \mathcal{W} \)-orbit segment \([x'_0, y'_n]_\mathcal{W}\) is obtained by an inductive “short-cut” procedure, which replaces the “dynamics” of the Kuperberg flow with that of the Wilson flow.

6. Dynamics and level

In this section, we consider when it is possible to perform an inverse of the short-cut reduction used in Section 5 which replaces a \( \mathcal{W} \)-arc with a suitable \( \mathcal{K} \)-orbit segment that spans the gap between the endpoints of a \( \mathcal{W} \)-orbit segment. The solution to this problem depends on the relations between the functions \( \rho_x(t) \), \( n_x(t) \), and the lengths of \( \mathcal{W} \)-orbit segments in \( \mathcal{W} \) as will be shown below. An important application of this analysis gives criteria for when the \( \mathcal{K} \)-orbit of a point \( x \in \mathcal{K} \) must necessarily escape through a face of \( \mathcal{K} \), either in forward or backward time.

Recall that \( D_i = \sigma_i(D_i) \subset \mathcal{W} \) is the inserted compact region. Define

\[
R_* = \max\{R_1, R_2\} \quad R_i = \max\{r(x) \mid x \in D_i\} > 2
\]

Note that for any \( x \in \mathcal{W} \) with \( r(x) > R_* \), the \( \mathcal{W} \)-orbit of \( x \) in \( \mathcal{W} \) does not intersect the inserted regions \( D_i \), but it might intersect the regions \( D_i \). Hence the \( \mathcal{K} \)-orbit of \( \tau(x) \in \mathcal{K} \) escapes through the top face \( \partial^n_K \mathcal{K} \) of \( \mathcal{K} \) or intersects the secondary exit regions \( S_i \) for \( i = 1 \) or 2 in forward time, and escapes through the bottom face \( \partial^1_K \mathcal{K} \) or intersects the secondary entry regions \( E_i \) for \( i = 1 \) or 2 in backward time. Also, for the case where \( r(x) = R_* \), the orbit of \( \tau(x) \in \mathcal{K} \) behaves in the same way as the flow on the boundary of \( D_i \) agrees with the Wilson flow on \( \mathcal{W} \).

Let \( C(r) = \{x \in \mathcal{W} \mid r(x) = r\} \) denote the cylinder in \( \mathcal{W} \) of radius \( r \), with \( C(2) = C \) as defined in Section 2. Observe that the entry regions \( E_i \) for \( i = 1, 2 \) intersect the cylinders \( C(r) \) for \( 1 \leq r \leq R_* \) in lines. Then for \( 1 < r \leq R_* \), the radius inequality and the compactness of \( C(r) \) imply there exists a lower bound

\[
\delta(r) = \min\{r(\sigma_i^{-1}(x)) \mid x \in C(r) \cap E_i\} \quad i = 1, 2 \geq r
\]

with equality only for \( r = 2 \). Note that \( \delta(2) = 2 \) and \( \delta(R_*) = 3 \), and that \( \delta(r) \) is an increasing function of \( r \). The graph of \( r \mapsto \delta(r) \) is illustrated in Figure 12.

Fix \( r_0 > 2 \), set \( r_1 = \delta(r_0) \) and define \( r_k = r_{k-1} \) recursively, if \( r_{k-1} \leq R_* \). By the compactness of the regions \( D_i \) there exists \( N(r_0) \geq 0 \) such that \( r_k \leq R_* \) for \( k < N(r_0) \), but \( r_k > R_* \) for \( k = N(r_0) \). Note that \( r_k \) is not defined for \( k > N(r_0) \).

We make an observation concerning the hypothesis “\( x \) is not a secondary exit point” which is often imposed in the statements of the following results. Consider the level function \( n_x(t) \) for the case where \( x \in \mathcal{K} \) is a secondary exit point. For \( \epsilon > 0 \) sufficiently small so that the orbit segment \( \{\Phi_t(x) \mid 0 < t \leq \epsilon\} \) contains no
transition point, then we have that \( n_x(t) = 0 \) for \( 0 \leq t < \epsilon \) by the definition \[\text{[12]}\]. Recall that the radius function \( r(x) = r(\tau^{-1}(x)) \) on \( \mathbb{K} \) has a discontinuity at a secondary exit point, where \( r(x) = r(x') \) for \( x' \in D_i \) with \( \tau(x') = x \). As \( x \) is a secondary exit point, we have that \( \rho_x(t) = r(\Phi_t(x)) = r(x'') \) for \( 0 < t < \epsilon \) where \( x'' = \sigma_i(x') \) as in \[\text{[3]}\]. By the Radius Inequality (K8), we have \( r(x'') < r(x') \) unless \( r(x') = r(x'') = 2 \) where \( x \) is a special point. Thus, if \( x \) is a secondary exit point with \( r(x) > 2 \), we have that \( \rho_x(t) < r(x) \) for \( 0 < t < \epsilon \). The assumption \( x \) is not a secondary point eliminates this possibility.

We now give a sequence of results relating the level function with the properties of the orbits of \( \Phi_t \). First, we show that \( N(r_0) \) gives a uniform bound on the level function for forward \( K \)-orbits. In what follows, when we say “for all \( t \)” we mean “for all \( t \) such that \( \Phi_t(x) \) is defined”.

**Lemma 6.1.** Let \( r_0 > 2 \). Suppose that \( x \in \mathbb{K} \) with \( r(x) \geq r_0 \) and that \( n_x(t) \geq 0 \) for all \( t \geq 0 \). If \( x \) is not a secondary exit point, then \( n_x(t) \leq N(r_0) \) for all \( t \geq 0 \).

**Proof.** Suppose there exists \( t_* > 0 \) such that \( n_x(t_*) > N(r_0) \). We show this leads to a contradiction. Let \( x_t = \Phi_{t_*}(x) \) with \( 0 \leq t_0 < t_1 < \cdots < t_m < t_* \) be the transition points for \( \{\Phi_t(x) \mid 0 \leq t \leq t_*\} \).

Suppose there exists \( k > 1 \) such that \( n_x(t_{k-1}) = n_x(t_0) = 0 \). Then the segment \( [x_0, x_k]_K \) satisfies the hypotheses of Proposition \[5.5\] so we have \( x_0 <_W x_k \) and thus \( r(x'_{k-1}) = r(x) \geq r_0 \). The length of the \( W \)-orbit containing the segment \( [x_0, x_k]_W \) is bounded above by \( L(\epsilon) \) for \( \epsilon = r_0 - 2 \), from Lemma \[4.3\]. Hence there can exist at most a finite number of values \( k > 1 \) for which \( n_x(t_{k-1}) = n_x(t_0) = 0 \).

Let \( k \geq 0 \) be the largest index such that \( n_x(t_{k-1}) = n_x(t_0) = 0 \). Set \( \ell_1 = k \). Then the segment \( [x_0, x_{\ell_1}]_K \) satisfies the hypotheses of Proposition \[5.5\] so we have \( x_0 <_W y_{\ell_1} \) and thus \( r(x_\ell_{j-1}) = r(x) \geq r_0 \). As \( n_x(t) \geq 0 \) for all \( t \geq 0 \), we must have \( 1 = n_x(t_{\ell_1}) > n_x(t_{\ell_1-1}) \) and thus \( x_{\ell_1} \) is a secondary entry point, and so \( r(x_{\ell_1}) \geq r_1 \).

The assumption that \( \ell_1 \) is maximal implies that \( n_x(t) > 0 \) for \( t \in [t_{\ell_1}, t_{\ell_2}] \). Then if \( n_x(t_{\ell_1}) = 1 < N(r_0) \), then repeat the above process to choose \( \ell_2 \) to be the largest index such that \( n_x(t_{\ell_2-1}) = 1 \).

Continuing in this way for \( j < N(r_0) \), choose the sequence \( 0 = \ell_0 < \ell_1 < \cdots < \ell_n \) where \( n \leq N(r_0) \) as long as possible, such that \( \ell_j \) is the largest index satisfying \( n_x(t_{\ell_j-1}) = j - 1 \) and \( n_x(t_{\ell_j}) = j \), for \( 0 < j \leq n \). Then \( r(x_{\ell_j}) \geq \delta(r(x_{\ell_{j-1}})) \geq \delta(r_{j-1}) = r_j \) since \( x_{\ell_j} \) is a secondary entry point and \( r(x_{\ell_{j-1}}) = r(x_{\ell_{j-1}}) \geq r_{j-1} \).

The assumption \( n_x(t_*) > N(r_0) \) implies it is possible to choose an index \( n \) such that \( n_x(t_n) = N(r_0) \). By the choice of \( N(r_0) \) we have \( r_n > R_* \) and \( n_x(t_n) > N(r_0) \) for all \( t \geq t_n \), and hence the forward \( K \)-orbit \( \{\Phi_t(x) \mid t \geq t_n\} \) does not contain a transition point. Thus, \( \rho_x(t) \) is constant for \( t \geq t_n \) and hence the maximum value of \( n_x(t) \) is achieved at \( t = t_n \), where the value is \( N(r_0) \). This contradicts the assumption that \( n_x(t_*) > N(r_0) \).

**Corollary 6.2.** Suppose that \( x \in \mathbb{K} \) satisfies \( \rho_x(t) \geq r_0 > 2 \) for all \( t \geq 0 \). Then there exists \( n(r_0) \) such that \( n(r_0) \leq n_x(t) \leq N(r_0) \) for all \( t \geq 0 \).

**Proof.** Suppose no such lower bound on \( n_x(t) \) exists. Let \( x_t = \Phi_{t_{\ell_k}}(x) \) with \( 0 < t_0 < t_1 < \cdots < t_n < \cdots \) be the transition points in \( K \)-orbit \( \{\Phi_t(x) \mid t \geq 0\} \) and \( \ell_k \mid k = 1, 2, \ldots \) be an increasing subsequence such that \( n_x(t_{\ell_k}) = -k \).
Consider the flow $\Xi_t^k(x) = \Phi_{t \ell_k}^{-t}(x)$ on $\mathbb{K}$, then $\Xi_0^k(x) = x_{\ell_k}$ and $\Xi_t^k(x) = x$. Moreover, $r(\Xi_t^k(x)) \geq r_0$ for all $0 \leq t \leq t_{\ell_k}$. Then the level with respect to the flow $\Xi_t^k$ starting at $x_{\ell_k}$ increases to $k$ for $0 \leq t \leq t_{\ell_k}$. We can then apply the method of proof of Lemma 6.1 to conclude that the level is bounded above by $N(r_0)$, independent of the choice of $k$, which contradicts the above.

These results combine to yield an “escape” result for $\mathbb{K}$-orbits.

**Proposition 6.3.** Let $x \in \mathbb{K}$ satisfy $r_0 = r(x) > 2$, assume that $x$ is not a secondary exit point and suppose that $n_x(t) \geq 0$ for all $t \geq 0$. Then the forward $\mathbb{K}$-orbit of $x$ is not trapped.

**Proof.** Suppose that the forward orbit of $x$ is trapped, then there exists $0 \leq t_0 < t_1 < \cdots < t_n < \cdots$ so that the points $x_t = \Phi_{t \ell_t}(x)$ are the forward transition points for the $\mathbb{K}$-orbit $\{\Phi_t(x) \mid t \geq 0\}$. By Lemma 6.1 and our assumption, we have that $0 \leq n_x(t_\ell) \leq N(r_0)$ for all $\ell \geq 0$.

Let $0 \leq n_0 < N(r_0)$ be the least integer such that there exists $0 \leq t_0 < t_1 < \cdots < t_k < \cdots$ such that $n_x(t_\ell) = n_0$. That is, $n_0 = \liminf_{\ell \to 0} n_x(t_\ell)$. Since $n_0$ is the least such integer, there exists $k \geq 0$ such that $n_x(t) \geq n_0$ for all $t \geq t_k$. Then for each integer $\alpha \geq 1$, the segment $[x_{\ell_k}, x_{\ell_{k+\alpha}}]$ satisfies the hypotheses of Proposition 5.5 so we have $x_{\ell_k} \prec \mathbb{W} y_{\ell_{k+\alpha}}$. Then by Lemma 4.3 and Corollary 4.5, considering the lengths of the lifted $\mathbb{W}$-orbit segments $[x_{\ell_k}, y_{\ell_{k+\alpha}}]$, we have that $d_{\min} \cdot (\ell_{k+\alpha} - \ell_{k}) \geq L(r_0 - 2)$ for all $\alpha$. However, we can choose $\ell_{k+\alpha}$ arbitrarily large and hence also $(\ell_{k+\alpha} - \ell_k)$, which yields a contradiction. □

**Corollary 6.4.** Let $x \in \mathbb{K}$ satisfy $\rho_x(t) > 2$ for all $t \geq 0$, and suppose that $\liminf_{t \to 0} n_x(t) > -\infty$. Then the forward $\mathbb{K}$-orbit of $x$ is not trapped.

**Proof.** Let $t_0 \geq 0$ be such that $x_0 = x_{t_0} = \Phi_{t_0}(x)$ is a transition point with $n_x(t_0) = \liminf_{t \to 0} n_x(t)$. Then $n_x(t_0) \geq 0$ for all $t \geq t_0$ and we have $r(x_0) > 2$. Then apply Proposition 6.3 for $x = x_0$. □

Ghys remarks in [17, Lemme, page 300], that for an entry point $x \in \mathbb{K}$ which escapes to its facing exit point $y$, so that $x \equiv y$, “the $\mathbb{K}$-orbit of $x$ contains the image under $\tau$ of all the $\mathbb{W}$-arcs that lie in $\mathbb{W}'$ between $x'$ and $y'$, where $y'$ is the exit point such that $x' \equiv y'$.” Propositions 6.5 and 6.7 below give a precise formulation of this assertion. Figure 13 illustrates these lifts.

**Proposition 6.5.** Let $x' \in \mathbb{W}$ such that $x = \tau(x')$ is a primary entry point in $\mathbb{K}$ with $r(x) > 2$. Then the $\mathbb{K}$-orbit of $x$ escapes from $\mathbb{K}$ at some primary exit point $w$, we have that $\rho_x(t) \geq r(x)$ for all $t$ and the collection of lifts of the $\mathbb{W}$-arcs in $[x,w]_\mathbb{K}$ contains all the $\mathbb{W}$-arcs of the $\mathbb{W}$-orbit of $x'$ that are in $\mathbb{W}$.

**Proof.** Suppose that the forward orbit of $x$ is trapped, then there exists $0 = t_0 < t_1 < \cdots < t_n < \cdots$ with $x_t = \Phi_{t \ell_t}(x)$ the transition points for the $\mathbb{K}$-orbit $\{\Phi_t(x) \mid t \geq 0\}$. We claim that $n_x(t) \geq 0$ for all $t \geq 0$, then the result follows from Proposition 6.3 and Proposition 6.6.

Suppose $n_x(t_0) < 0$ for some $t_0 > 0$, then there is a least $k > 0$ such that $n_{x_0}(t_k) = -1$, and thus $n_{x_0}(t_{k-1}) = 0$ and $x_k$ is an exit point. Proposition 5.5 then implies that $x'_0 \prec \mathbb{W} x'_k$ and $x_0 \equiv x_k$. Since $x_0$ is a primary entry point, we must have that $x_k$ is a primary exit point, which is a contradiction. Thus, $n_{x_0}(t) \geq 0$ for all $t \geq 0$.

Next, note that as $x_0$ is a primary entry point, $[x'_0, y'_0]_\mathbb{K} \subset \hat{\mathbb{W}}$ is the initial $\mathbb{W}$-arc in the intersection of the $\mathbb{W}$-orbit of $x'$ with $\hat{\mathbb{W}}$. Then let $\ell_1, \ell_2, \ldots, \ell_m$ be the collection of all the indices such that $n_{x_0}(t_{\ell_{k-1}}) = 0$ for all $k = 1, 2, \ldots, m$. Proposition 5.5 implies that $x'_0 \prec \mathbb{W} y'_t$ and $x_1 \equiv x_{\ell_1}$, hence the subsequent lift $[x'_{\ell_1-1}, y'_{\ell_1}]_\mathbb{K} \subset \hat{\mathbb{W}}$ is the second arc in the intersection of $\mathbb{W}$-orbit of $x'_0$ with $\hat{\mathbb{W}}$. Continuing by induction, we obtain that all the $\mathbb{W}$-arcs for $x'_0$ lying in $\hat{\mathbb{W}}$ are contained in the $\mathbb{K}$-orbit of $x_0$. □

There is an important consequence of this result.
**COROLLARY 6.6.** Let \( z \in \mathbb{K} \) satisfy \( r(z) > 2 \) and \( n_z(t) \geq 0 \) for all \( t \geq 0 \). Then the forward \( \mathcal{K} \)-orbit of \( z \) exits \( \mathbb{K} \) in a point \( y = \Phi_T(z) \) at which \( n_z(T) = 0 \). Furthermore, \( z \) is contained in a bounded orbit of \( \Phi_t \), starting at a primary entry point \( x \) of \( \mathbb{K} \), where \( x \equiv y \).

**Proof.** Proposition 6.3 implies that the flow \( \Phi_t \) has a primary exit point \( y \) at time \( T \). Note that \( n_z(T) \geq 0 \) implies \( r(y) \geq r(z) > 2 \) by Proposition 5.5.

Then apply Proposition 6.5 to the reverse flow \( \Xi_T(t) = \Phi_{T-t}(\xi) \) to deduce that there exists \( t_\ast \geq T \) such that \( x = \Xi_T(t_\ast) \) is a primary exit point for \( \Xi_T(t) \) and hence a primary entry point for \( \Phi_t \). Moreover, the proof of Proposition 6.5 shows that \( n_x(t) \geq 0 \) for all \( t \geq 0 \). Note that \( y = \Phi_T(z) = \Phi_{t_\ast}(x) \) so we also have \( n_x(t_\ast) = 0 \).

The fact \( n_z(T) = 0 \) follows form the equality \( n_z(t) = n_x(t_\ast + t) - n_z(t_\ast) \) for all \( t \geq 0 \). Thus \( n_z(T) = n_x(t_\ast) - n_z(t_\ast) = -n_z(t_\ast + T) \leq 0 \). Since \( T \geq 0 \) and \( n_z(T) \geq 0 \) by hypothesis, \( n_z(T) = 0 \) as claimed.

The conclusion of Corollary 6.6 has a simple geometric interpretation. Given a primary entry point \( x \in \mathbb{K} \) with \( r(x) > 2 \), the points \( z = \Phi_t(x) \) along the \( \mathcal{K} \)-orbit of \( x \) for which \( n_x(t) = 0 \) are exactly those in the Wilson flow of \( x' \) which lie in \( \hat{\mathbb{W}} \). Proposition 6.5 implies that each such \( \mathcal{W} \)-arc of the \( \mathcal{W} \)-orbit of \( x' \) contains all the \( \mathcal{W} \)-orbits of the \( \mathcal{W} \)-orbit of \( x' \) that are in \( \hat{\mathbb{W}} \), where \( \tau(x') = x \). Hence, if \( [x', y]_\mathcal{W} \) and \( [y', z']_\mathcal{W} \) are \( \mathcal{W} \)-arcs, then their images under \( \tau \) are both contained in the \( \mathcal{K} \)-orbit through \( x \).

**PROPOSITION 6.7.** Let \( x \in \mathbb{K} \) be a secondary entry point with \( r(x) > 2 \), let \( y \) be a secondary exit point and suppose that \( z \equiv y \). Then \( x \prec_\mathcal{K} y \) and the collection of lifts of the \( \mathcal{W} \)-arcs in \( [x, y]_\mathcal{K} \) contains all the \( \mathcal{W} \)-arcs of the \( \mathcal{W} \)-orbit of \( x' \) that are in \( \hat{\mathbb{W}} \), where \( \tau(x') = x \). Hence, if \( [x', y']_\mathcal{W} \) and \( [y', z']_\mathcal{W} \) are \( \mathcal{W} \)-arcs, then their images under \( \tau \) are both contained in the \( \mathcal{K} \)-orbit through \( x \).

**Proof.** Corollary 6.6 implies there exists a maximal \( t_\ast > 0 \) such that \( n_x(t) \geq 0 \) for \( 0 \leq t < t_\ast \) as \( x \) is assumed to be a secondary entry point. Then \( x_\ast = \Phi_{t_\ast}(x) \) must be an exit point.

Let \( 0 = t_0 < t_1 < \cdots < t_n = t_\ast \) with \( x_i = \Phi_{t_i}(x) \) be the transition points for the \( \mathcal{K} \)-orbit \( \{ \Phi_t(x) \mid 0 \leq t \leq t_n \} \). Then \( n_x(t) \geq 0 \) for all \( 0 \leq t < t_n \), and \( n_x(t_{n-1}) = 0 \). Hence \( x_{n-1} \) and \( x_n \) are exit points. By Proposition 6.5, \( x_0 \prec_\mathcal{W} y'_0 \) and \( x_0 \equiv x_n \). The point facing \( x \) is unique, so we must have \( y = x_n = \tau(y'_n) \) and \( x \prec_\mathcal{K} y \).

The proof that the segment \( [x, y]_\mathcal{K} \) contains all the \( \mathcal{W} \)-arcs on the \( \mathcal{W} \)-orbit of \( x' \) that are in \( \hat{\mathbb{W}} \) follows as in the proof of Proposition 6.5. The first transition point \( x_1 \) must be a secondary exit as \( n_x(t_1) \geq 0 \), thus \( n_x(t_1) = 1 \). If \( n_x(t_2) = 0 \) then \( x_2 \) is a secondary exit, so by Proposition 6.5 we have that \( x' \prec_\mathcal{W} x'_3 \) and so...
\(x_1 = x_2\). Thus the lift of the \(W\)-arc \([x_2, x_3]_K\) is contained in the \(W\)-orbit of \(x'\). Otherwise, \(n_x(t_2) = 2\) and we continue the analysis of cases, until we obtain the first instance where \(n_x(t_{l-1}) = 0\). We can then apply Proposition 5.5 to conclude that \(x'_0 \prec_W y'_1\). Thus the lift of the \(W\)-arc \([x_{l-1}, x_l]_K\) is contained in the \(W\)-orbit of \(x'\). The rest follows as in the proof of Proposition 6.5.

Let \(x' \in \partial_h^\pm W\) with \(r(x') > 2\) and let \(y' \in \partial_h^\pm W\) be the unique facing point. Let \(x = \tau(x')\) and \(y = \tau(y')\). If \(x\) is a primary entry point, then \(x \prec_K y\) by Proposition 6.5. If \(x\) is a secondary entry point, then \(x \prec_K y\) by Proposition 6.7. Thus, in both cases there exists \(T_x > 0\) such that \(\Phi_{T_x}(x) = y\).

**COROLLARY 6.8.** The function \(x' \mapsto T_{x'}\) is well-defined and continuous for \(x' \in \partial_h^\pm W\) with \(r(x') > 2\). Moreover, \(T_{x'}\) tends to infinity as \(r(x')\) tends to 2.

## 7. Trapped and infinite orbits

In this section, we begin the analysis of the trapped orbits of the flow \(\Phi_t\). We first consider the orbits of points \(x = \tau(x')\) with \(r(x') = 2\). The following result is a general formulation of an observation of Kuperberg, which provided the original insight leading to her construction [29] and was sketched in Figure 10.

**PROPOSITION 7.1.** Let \(x' \in \mathbb{W}'\) with \(r(x') = 2\) and set \(x = \tau(x')\). Then the \(K\)-orbit of \(x\) is trapped in either forward or backward time, or both. Moreover, the collection of \(W\)-arcs for the \(K\)-orbit of \(x\) contains every \(W\)-arc lying in \(\hat{\mathbb{W}}\) of the \(W\)-orbit of \(x'\) and there is a sequence \(\{x'_j | j = 1, 2, \ldots\}\) of transition points with \(r(x'_j) = 2\) such that \(\{x_{\ell_j} = \tau(x'_j) | j = 1, 2, \ldots\}\) converges to a special point \(p^-_{i}\) for \(i = 1, 2\).

**Proof.** Assume without loss of generality that \(x\) is not a transition point and let \(x_t = \Phi_t(x), 0 < t_0 < t_1 < \cdots < t_n < \cdots\), be the transition points for the \(K\)-orbit \(\{\Phi_t(x) | t \geq 0\}\). There are five cases to consider:

1. \(z(x') = -1\);
2. \(z(x') = 1\);
3. \(\tau = \tau(x) < -1\);
4. \(-1 < z(x') < 1\);
5. \(1 < z(x') \leq 2\).

Consider first the case of the forward \(K\)-orbit of a point \(x = \tau(x')\) with \(x' \in \mathbb{W}'\), \(r(x') = 2\) and \(z(x') = -1\). Then \(x_0 \in E_0\) is the special point \(p^-_1\) of (11) and for the \(W\)-arc \(\{x'_0, y'_1\}_W \subset \mathbb{W}'\) we have \(x'_0 \in L^-_1 \subset \partial^-_h W\). Then \(r(x'_0) = 2\) by Condition (K7) so that \(r(y'_1) = 2\) also. The \(W\)-arc \(\{x'_0, y'_1\}_W\) flows upward from \(x'_0 = -2\) until it intersects at \(y'_1 \in L^-_1\), with \(z(y'_1) < -1\), as in Figure 10. Let \(x'_1 \in L^-_1\) satisfy \(\tau(x'_1) = \tau(y'_1)\), then the Radius Inequality implies that \(r(x'_1) > 2\). Let \(\tau_1 \in S_1\) be the facing point to \(x_1\). Then by Proposition 6.7, we have \(x_1 \prec_K \tau_1\) and so \(\tau_1 = x_{\ell_1 - 1}\) for some \(\ell_1 \geq 2\). Then \(r(x'_{\ell_1 - 1}) = 2\), \(z(y'_1) < z(x'_{\ell_1 - 1}) < -1\) and \(\{x_{\ell_1 - 1}, y'_{\ell_1}\}_W\) is the subsequent \(W\)-arc. Thus \(x_{\ell_1} = \tau(y'_{\ell_1})\) must be a secondary entry point again and we can repeat this argument inductively to obtain a subsequence \(\{y'_{\ell_i} | i = 1, 2, \ldots\}\) in \(L^-_1\) with \(x_{\ell_i} = \tau(y'_{\ell_i})\) in \(E_1\) converging to \(p^-_1\), so that the forward orbit of \(x\) is trapped. The assertion about the collection of lifts of \(W\)-arcs in \(\hat{\mathbb{W}}\) follows from Proposition 6.7. A similar analysis for the backward orbit of \(x\) yields a subsequence of transition points converging to \(p^-_2\). For the case of \(x = \tau(x')\) with \(x' \in \hat{\mathbb{W}}\) and \(r(x') = 2\) and \(z(x') = 1\), that is the first forward transition point \(x_0 \in E_2\) is the special point \(p^-_2\) of (11) and so for the \(W\)-arc \(\{x'_0, y'_1\}_W \subset \mathbb{W}'\) we have \(x'_0 \in L^-_2 \subset \partial^-_h \mathbb{W}'\). Then again \(r(x'_0) = 2\) by Condition (K7) and the rest of the analysis proceeds similarly to the previous case. Note that the forward orbits of a point \(x = \tau(x')\) in the two cases where \(r(x') = 2\) and \(z(x') = \pm 1\) limit to \(p^-_1\), while their backward orbits tend to \(p^-_2\).

There are three remaining cases: either \(-2 < z(x') < -1\), \(-1 < z(x') < 1\), or \(1 < z(x') \leq 2\). All three cases proceed in a manner analogous to the two cases above.
If $-2 < z(x') < -1$, then the forward $W$-orbit of $x'$ is asymptotic to the periodic orbit $O_1$, so in particular is trapped for the Wilson Plug and each time the $W$-orbit enters an insertion region $D_i \subset W$, it subsequently exits through the facing point. Thus, the forward $K$-orbit of the point $x = \tau(x')$ has first transition point $x_0 \in E_1$. As $x'$ is not in a periodic orbit, we have $x_0 = \tau^{-1}(x_0) \in L^-_1$ with $r(x_0') > 2$. Let $x_{t_i} \in S_1$ be the facing point, by Proposition 6.7 $x_0 \prec_{K} x_{t_{i-1}}$. We then proceed as above, to obtain a subsequence $\{x_{t_i} | i = 0, 1, 2, \ldots \}$ in $E_1$ with $x_{t_i}$ converging to $p_1$.

Note that the backward $W$-orbit of $x'$ is not trapped and so exits $W$ at a point $y'$. The backward $K$-orbit of $x$ contains the point $y = \tau(y')$. If $y \notin L^-_1$ for $i = 1, 2$, then the backward $K$-orbit of $x$ is not trapped. If $y \in L^-_1$ for $i = 1, 2$, then the process continues in the backward direction.

For the case $-1 < z(x') < 1$, the forward $W$-orbit of $x'$ in $W$ is asymptotic to the periodic orbit $O_2$, and each time the $W$-orbit enters an insertion region $D_i$ it subsequently exits the same region. The rest of the analysis proceeds similarly to the case when $-2 \leq z(x') < -1$, yielding a subsequence of secondary entry points for the forward $K$-orbit which converge to $p_2$. The backward $W$-orbit of $x'$ in $W$ is asymptotic to the periodic orbit $O_1$, yielding in the same manner a subsequence of secondary entry points for the reverse $K$-orbit converging to $p_1$.

The last case, for $1 < z(x') \leq 2$, reduces to the case for $-2 \leq z(x') < -1$ by reversing the flow $\Phi_t$. Thus, the forward $K$-orbit of $x$ may escape through $\partial_h^+ K$ or may be trapped for all forward time. The backward $W$-orbit of $x'$ always converges to $O_2$ and so yields a subsequence of secondary entry points for the reverse flow converging to $p_2$.

We observe two additional consequences of Proposition 7.1 and its proof.

**COROLLARY 7.2.** Let $x \in K$ and suppose that either $x$ is a primary entry point with $r(x) = 2$, or $x = \tau(x')$ where $x' \in O_i \cap W'$ for $i = 1, 2$. Then the level function based at $x$ satisfies $n_x(t) \geq 0$ for all $t \geq 0$. Moreover, if $\Phi_t(x)$ is not a transition point for $t \geq 0$, then $n_x(t) = 0$ if and only if $\rho_x(t) = 2$.

**COROLLARY 7.3.** Let $x \in K$ and suppose there exists $t_* \in \mathbb{R}$ such that $y = \Phi_{t_*}(x)$ is a secondary entry point with $\rho_x(t_*) = 2$. Then for all $t > t_*$ we have that $\rho_x(t) \geq 2$. Moreover, the forward orbit of $x$ contains an infinite sequence of secondary entry points that limit to $p_1 \in E_1$ for $i = 1$ or $i = 2$.

We next consider the $K$-orbits of points $x \in K$ for which $r(x) < 2$. We recall results by Ghys [17] and Matsumoto [34], which give conditions such that the orbit of $x$ is trapped in forward time and that the closure of the $K$-orbit of $x$ contains a special point. Hence the closure of the $K$-orbit of $x$ contains the closures of the orbits of both special points $p_1$ and $p_2$.

Fix $i = 1, 2$ and consider the restriction of the insertion map $\sigma_i : L^-_i \to D_i \subset W$. Express this map in polar coordinates $(r', \theta')$ on the domain $L^-_i$ and $(r, \theta, z)$ on the image. The image under $\sigma_i$ of the curve $\{r' = 2\} \cap L^-_i$ is a “parabolic curve” $\Upsilon$ which is tangent to the vertical line $\{r = 2\}$. For each $i = 1, 2$, we define two regions (see Figure 14) contained in the image of the region $L^-_i \cap \{r < 2\}$:

- $\mathcal{E}^-_{i} = \sigma_i(\{r' < 2\} \cap L^-_i) \cap \{r < 2\}$ with outer boundary $\Upsilon$
- $\mathcal{E}^+_{i} = \sigma_i(\{r' > 2\} \cap L^-_i) \cup \{r < 2\}$ with inner boundary $\Upsilon$.

We make two basic observations, as used in the proof of [34 Proposition 7.1]. First, the tangency of $\Upsilon$ with the vertical line $\{r = 2\}$ and Taylor’s Theorem implies that for $\delta > 0$ sufficiently small, the vertical line segment $\mathcal{E}^-_{i} \cap \{r = 2 - \delta\}$ has length at least $C' \cdot \sqrt{\delta}$ for some fixed $C' > 0$.

The second observation is that the Wilson vector field $W$ is horizontal along the periodic orbits $O_i$ as the vertical component $g(r, \theta, z) \frac{\partial}{\partial z}$ in [3] vanishes at the points $(2, \theta, \pm 1)$. Thus, there exists $C'' > 0$ so that for $\delta > 0$ sufficiently small, the flow $\Psi_t(x')$ of a point $x' \in W$ with $r(x') = 2 - \delta$ intersects the face $L^-_i$ in a sequence of points whose vertical spacing near the planes $\{z = \pm 1\}$ is bounded above by $C'' \cdot \delta$. A more precise estimate can be obtained using the method of proof for Lemma 17.3, but these approximate results suffice for the proof of Proposition 7.3 below.
The Matsumoto region $32$ STEVEN HURDER AND ANA RECHTMAN

DEFINITION 7.4. We say that $\delta_M > 0$ is a Matsumoto constant if for all $0 < \delta \leq \delta_M$ and $C', C''$ as above, then

(20) $C'' \cdot \delta < C' \cdot \sqrt{\delta}$

The Matsumoto region for $\delta_M$ is the set $\mathcal{U}(\delta_M) = \tau(\{2 - \delta_M < r < 2\}) \subset \mathbb{R}$.

PROPOSITION 7.5. [4] Proposition 7.1] Let $\delta_M > 0$ be a Matsumoto constant, and $x = \tau(x') \in \mathcal{U}(\delta_M)$.

1. If $z(x') = -2$, then the forward orbit of $x$ is trapped. Moreover, there exists a subsequence of transition times, $0 < t_0 < t_1 < \cdots < t_i < \cdots$, such that $r(x'_t) \leq 2$ for $0 \leq i \geq 0$ with $\lim_{i \to \infty} r(x'_t) = 2$.

2. If $z(x') = 2$, then the backward orbit of $x$ is trapped. Moreover, there exists a subsequence of transition times, $0 > t_0 > t_1 > \cdots > t_i > \cdots$, such that $r(x'_t) \leq 2$ for $0 \leq i \geq 0$ with $\lim_{i \to \infty} r(x'_t) = 2$.

3. If $z(x') = 0$, then the orbit of $x$ is infinite and there exists a bi-infinite subsequence of transition times such that $r(x'_t) \leq 2$ for all $i$, with $\lim_{i \to \infty} r(x'_t) = 2$.

Proof. We consider first the case $z(x') = -2$. The case $z(x') = 2$ follows analogously, by reversing the flow $\Phi_t$. Figure 14 illustrates the following construction.

Given $x'_0 = (r_0, \theta, -2)$ which satisfies $2 - \delta_M < r_0 < 2$, the $\mathcal{W}$-orbit of $x'_0$ has increasing $z$-coordinate in $\mathcal{W}$ and intersects the face $L^{-}$ in the set $\mathcal{E}_i^{+, -}$, possibly repeatedly, until it first intersects either the curve $\mathcal{Y}$ or the region $\mathcal{E}_i^{+, -}$. If $\Phi_t(x'_0) \in \mathcal{Y}$ for some $t_0 > 0$, then $r(\tau(\Phi_t(x'_0))) = 2$ and the analysis of the forward orbit reduces to the case of Corollary 7.3.

Otherwise, the assumption that $2 - \delta_M < r_0 < 2$ implies the initial segment of the $\mathcal{K}$-orbit of $x_0 = \tau(x'_0)$ contains a sequence of $\mathcal{W}$-arcs which coincide with the initial $\mathcal{W}$-arcs of the $\mathcal{W}$-orbit of $x'_0$, up until the initial point of the $\mathcal{W}$-arc that is contained in $\mathcal{E}_i^{+, -}$. Then the $\mathcal{K}$-orbit jumps to a radius $r_1$ with $\delta_M < r_0 < r_1 < 2$ and this pattern repeats itself. We make this sketch of proof precise.

Let $x_\ell = \Phi_{\ell t}(x_0)$ with $0 = t_0 < t_1 < \cdots < t_n < \cdots$ be the transition points for the $\mathcal{K}$-orbit $\{\Phi_t(x_0) \mid t \geq 0\}$. Denote the corresponding lifts to $\mathcal{W}$ of the $\mathcal{W}$-arcs in this forward orbit by $[x'_t, y'_{t+1}]_\mathcal{W}$. As remarked above, we can assume that $r(x'_t) \neq 2$ for all $\ell$. The orbit of $x_0$ is then described by an iterative process, as follows.

Note that $x'_0 \in \partial_h \mathcal{W}$ implies that $y'_1 \in \mathcal{E}_1^{-}$, so $n_{x_0}(t_1) = 1$. If $x_1 \in \mathcal{E}_1^{+, -}$, set $\lambda_1 = 1$, $\eta_1 = x_1$ and $r_1 = r(\eta_1)$. Then note that $r(y'_1) = r(x'_0) = r_0$ while $r_0 < r(\eta'_1) < 2$ by the definition of the region $\mathcal{E}_1^{+, -}$.

Otherwise, we have $x_1 \in \mathcal{E}_1^{+, -}$ and so $r(y'_1) = r_0$ while $r(x_1') > 2$ by definition. Proposition 6.7 implies that there is a least $\ell_1 > 1$ such that $n_{x_0}(t_{\ell_1-1}) = 0$, so that $x_0$ and $x_{\ell_1}$ satisfy $x'_0 \sim_{\mathcal{W}} x'_{\ell_1-1}$ by Proposition 5.5 and $r(x'_{\ell_1-1}) = r_0$. Then $x_{\ell_1}$ is a secondary entry point.

If $x_{\ell_1} \in \mathcal{E}_i^{+, -}$ then set $\lambda_1 = \ell_1$, $\eta_1 = x_{\ell_1}$ and $r_1 = r(\eta_1)$. Otherwise, $x_{\ell_1} \in \mathcal{E}_i^{+, -}$ and so $r(x'_{\ell_1}) > 2$, and we repeat this process. By Corollary 4.6 and the choice of $\delta$, this inductive process can be repeated at most a
finite number of times, until we obtain \( \{0 = t_0 < t_1 < \cdots < t_{k_0}\} \) with \( r(x'_{t_{k_0}-1}) = r_0, r(x'_{t_i}) > 2 \) for \( 1 \leq i < k_0 \) and \( r_0 < r(x'_{t_{k_0}}) < 2 \). Thus \( x_{t_{k_0}} \in \mathcal{E}^+_i \). Then set \( \lambda_1 = t_{k_0}, \eta_1 = x_{\lambda_1} \) and \( r_1 = r(\eta_1) \).

We thus obtain the secondary entry points \( \{y'_i \mid 0 \leq i < k_0\} \subseteq \{r = r_0\} \cap \mathcal{L}_i^- \) all contained in a vertical line \( r = r_0 \), plus a new point \( \eta_1 \in E_1 \) with lifts \( y'_{\lambda_1} \subseteq \{r = r_0\} \cap \mathcal{L}_1^- \) and \( x'_{\lambda_1} = y'_1 \) and \( r_0 < r_1 = r(\eta_1) < 2 \). We can then repeat the above process by considering the \( K \)-orbit of \( \eta_1 \), which yields an ascending finite sequence of secondary entry points \( \{x'_i\} \) with \( \{y'_i\} \) contained in the vertical line segment \( \mathcal{E}^{-1}_{1} \cap \{r = r_1\} \), until they reach the point \( \eta_2 = x_{\lambda_2} \in \mathcal{E}^{-2}_{1} \) with radius \( r_0 < r_1 < r_2 = r(\eta_2) < 2 \).

This process then continues recursively, so that the sequence of transition points \( \{x_i \mid i \geq 0\} \) contains an infinite collection of finite subsequences lying on the lines \( \{r = r_j\} \cap \mathcal{L}_j^- \) with \( r_0 < r_1 < r_2 \), where the initial points \( \eta_j \) for each such “finite stack of points” is defined as the secondary entry points where the sequence transitions from the region \( \mathcal{E}^{-j}_{1} \) to the region \( \mathcal{E}^{-j}_{1} \). Moreover, the sequence of radii \( r_j \to 2 \) by the Radius Inequality. Finally, note that the forward \( K \)-orbit of \( x_0 \) satisfies \( r(\eta_1) < r(\eta_{i+1}) \) so the orbit cannot be recurrent.

![Figure 15. Trapped orbits intersecting \( \mathcal{E}^{-i}_{1} \) infinitely often](image)

As noted above, if \( x'_0 = (r_0, \theta, 2) \) with \( 2 - \delta_M < r_0 < 2 \), then we obtain a similar conclusion using the reverse time flow and the \( z \)-symmetry of the flow \( \mathcal{W} \) on \( \mathbb{W} \).

If \( x'_0 = (r_0, \theta, 0) \) with \( 2 - \delta_M < r_0 < 2 \), then the forward \( \mathcal{W} \)-orbit of \( x'_0 \) has increasing \( z \)-coordinate in \( \mathbb{W} \), and intersects the face \( \mathcal{L}_2^- \) in the set \( \mathcal{E}^{\pm}_{2} \), possibly repeatedly, until it first intersects either the curve \( \Upsilon \), or the region \( \mathcal{E}^{-2}_{2} \). The analysis then proceeds as above. The backward \( \mathcal{W} \)-orbit of \( x'_0 \) has decreasing \( z \)-coordinate in \( \mathbb{W} \), and we obtain a similar conclusion using the \( z \)-symmetry of the Wilson flow.

Suppose that \( r(x) < 2 \) and assume there exists \( t_0 > 0 \) such that \( \rho_x(t_0) = 2 \). Then by Corollary 7.3 the forward orbit \( \{\Phi_t(x) \mid t \geq t_0\} \) is trapped in the region \( \{r \geq 2\} \).

For \( r(x) < 2 \), it remains to consider the case where \( \rho_x(t) \neq 2 \) for all \( t \geq 0 \). The proof of the next result is adapted from the proof of the Théorème in [17] page 301.

**PROPOSITION 7.6.** Let \( x \in K \) satisfy \( r(x) < 2 \) and assume that its forward orbit is trapped and satisfies \( \rho_x(t) \neq 2 \) for all \( t \geq 0 \). Then there exists an infinite subsequence of transition points \( \{x_{t_i} \mid i = 1, 2, \ldots\} \) with \( r(x'_{t_i}) < 2 \) such that \( \lim_{i \to \infty} r(x'_{t_i}) = 2 \).
Proof. Let $x_t = \Phi_t(x)$ with $0 < t_0 < t_1 < \cdots < t_n < \cdots$ be the transition points for $\{\Phi_t(x) \mid t \geq 0\}$, with associated lifts of $W$-arcs $[x'_t, y'_{t+1}]_W$.

We first show that $r(x'_t) < 2$ for an infinite number of indices $t$. If not, then there exists $t_0 \geq 0$ which is the least index such that $r(x'_t) \geq 2$ for all $t \geq t_0$. As $r(x'_t) \neq 2$ for all $t \geq 0$, thus $r(x'_t) > 2$ for all $t \geq t_0$. In particular, the choice of $t_0$ implies that $r(x'_{t_0-1}) < 2$. Then $x_{t_0} \in E_i$ for $i = 1$ or $i = 2$, and let $\pi_{t_0} \in \mathbb{P}_{t_0}^+ \mathbb{L}_{t_0}$ be the facing point to $x'_{t_0} \in \mathbb{L}_{t_0}^-$. As $r(x'_{t_0}) > 2$, Proposition 6.7 implies that $x_{t_0} \prec W x'_{t_0}$ by Lemma 6.2 and so $r(x'_{t_0}) = r(y'_{t_0}) = r(x'_{t_0-1}) < 2$. This contradicts the choice of $t_0$, and thus the set of indices $t$ for which $r(x'_t) < 2$ must be infinite.

Next, we show that there exists a subsequence $\{x'_{t_i} \mid i = 1, 2, \ldots\}$ with $r(x'_t) < 2$ such that $\lim_{t \to \infty} r(x'_t) = 2$. Set $r_s = \limsup \{r(x'_t) \mid t \geq 0 \text{ such that } r(x'_t) < 2\}$ and let $\epsilon_s = 2 - r_s \geq 0$ and $r'_s = 2 - \epsilon_s/2 \leq 2$. Assume that $\epsilon_s > 0$, then we show this yields a contradiction.

Note that for all $0 < \epsilon < \epsilon_s$ the collection $\{x'_t \mid 2 - \epsilon \leq r(x'_t) < 2\}$ is finite by the definition of $r_s$. We can thus choose $t_s \geq 0$ so that $r(x'_t) < 2$ and satisfying the condition that for all $t \geq t_s$, if $r(x'_t) < 2$ then $r(x'_t) < r'_s$. Set $t_s = t_{i_s}$.

Observe that Radius Inequality (K8) implies that there exists $\delta_s^+ > 0$ so that if $r(x'_t) \leq r'_s$ and $x_{t_{i+1}}$ is a secondary entry point, then $r(x'_{t_{i+1}}) > r(x'_t) + \delta_s^+$. Conversely, the Radius Inequality also implies there exists $\delta_s^- > 0$ such that if $r(x'_t) \leq r'_s$ and $x_{t_{i+1}}$ is a secondary exit point, then $r(x'_{t_{i+1}}) < r(x'_t) - \delta_s^-$. Hence, $\delta_s = \min(\delta_s^+, \delta_s^-)$.

LEMMA 7.7. There exists a greatest lower bound $N_*$ such that $n_x(t) \geq N_*$ for all $t \geq 0$.

Proof. The set of values $\{n_x(t) \mid 0 \leq t \leq t_s\}$ is finite, so it suffices to show there is a lower bound on $n_x(t)$ when $t \geq t_s$.

If no such bound exists, then there exists an increasing subsequence of indices $\{t_i \geq t_s \mid i \geq 1\}$ with $n_x(t_k) = n_x(t_{k-1}) - 1$ and $n_x(t_{k+1}) = n_x(t_k) - i$ for all $i > 1$. Moreover, we can assume that $t_i$ is the least index $\ell > t$ such that $n_x(t) = n_x(t_{k-1}) - 1$. Consequently, each point $x_{t_i}$ must be a secondary exit point.

If $t_{i+1} > t_i + 1$, then $n_x(t_k) \geq n_x(t_{k+1})$ for $k < t_{i+1}$, and by Proposition 5.5 we have $x'_{t_i} \prec W y'_{t_{i+1}}$ and $r(x'_{t_i}) = r(y'_{t_{i+1}})$. For $i = 1$, this yields

$$r(x'_{t_1}) < r(x'_{t_1}) - \delta_s^- = r(x'_{t_1}) - \delta_s^+ < r'_s$$

so that $r(x'_{t_1}) < 2$. Then by induction, we have that $r(x'_{t_1}) < r(x'_{t_2}) - i \delta_s^- < r'_s - i \delta_s^-$ and in particular $r(x'_{t_s}) < 2$.

As $r(x'_{t_s}) \geq 1$ and $r'_s < 2$, the value of the index $i$ is bounded by $i \leq 1/\delta_s^-$, contradicting our assumption that the subsequence is infinite.

Let $N_* = \min\{n_x(t) \mid t \geq 0\}$, and let $0 < t_{t_1} < t_{t_2} < \cdots < t_{t_k}$ be the sequence of times such that $n_x(t_{t_i}) = N_*$. Note that the sequence $t_{t_k} < t_{t_{k+1}} < \cdots < t_{t_{k+1}}$ satisfies the hypotheses of Proposition 5.5 for each $i \geq 1$, and thus $x_{t_i} \prec W x'_{t_{i+1}}$ so $r(x'_{t_i}) = r(x'_{t_{i+1}})$. Then as in the proof of Proposition 6.3, this implies that $x'_{t_k} \prec W x'_{t_k}$ for all $i > 1$. However, $r(x'_{t_k}) < r'_s < 2$ by Lemma 4.3 the length of the $W$-orbit through $x'_{t_k}$ has an upper bound. This implies there is an upper bound on the number of $W$-segments $[x'_{t_k}, y'_{t_{k+1}}]_W$ which implies that $k$ is bounded above by a constant $k_1$ depending only on $r(x'_{t_k})$.

Then note that $n_x(t) \geq N_* + 1$ for all $t \geq t_{t_k+1}$. Repeat the above arguments inductively, to conclude that for each $i \geq 0$, there exists only a finite number of transition points $\{t_{i} \mid t \geq 0\}$ with $r(x'_{t_i}) < 2$ and $n_x(t_{i}) = N_* + i$. It follows that for some index $\ell > t_{k_1}$, we have that $r(x'_t) \geq r'_s$. However, $r'_s \leq r(x'_t) \leq 2$ is forbidden, so we obtain that $r(x'_t) > 2$ for all $\ell \geq t_k$ for $k$ sufficiently large. By Corollary 6.6 it follows that the orbit of $x_{t_k}$ escapes from $\mathbb{K}$, contrary to assumption.
Therefore, $r_* = 2$ and so there exists an infinite subsequence of transition points $\{x_{\ell_i} \mid i = 1, 2, \ldots\}$ with $r(x_{\ell_i}') < 2$ such that $\lim_{i \to \infty} r(x_{\ell_i}') = 2$.

Finally, note that the above proof shows that $\liminf_{k \to \infty} \{r(x_{\ell_k}') \mid \ell \geq k\} = 2$. \hfill $\square$

We point out a corollary of the proof of Proposition 7.6

**Corollary 7.8.** Suppose that $x \in K$ satisfies $\rho_x(t) < 2$ for all $t$, then $x$ is not trapped. \hfill $\square$

Finally, consider the case where $x \in K$ with $\rho_x(t) > 2$ for all $t \geq 0$. Sections 5 and 6 developed various criteria for when the orbit of $x$ is not trapped. For example, if the level function $n_x(t) \geq 0$ for all $t \geq 0$, then by Proposition 6.3 the $K$-orbit escapes. The techniques used above yield the following result for such trapped orbits. Note that later in this work, in Proposition 16.10 with the assumption of Hypotheses 12.1 and 12.2 we obtain a stronger conclusion about such orbits.

**Proposition 7.9.** Let $x \in K$ be trapped in forward time. If $\rho_x(t) > 2$ for all $t \geq 0$, then there exists a special point $p^*_j$ as in (11) and a subsequence $\{x_{\ell_i} \mid i = 1, 2, \ldots\}$ of forward transition points such that $\lim_{i \to \infty} x_{\ell_i}' = p^*_j$. The analogous result holds if $x$ is trapped in backward time.

Proof. By assumption, $r(x_{\ell_i}') > 2$ for all transition points $x_{\ell_i} = \Phi_{t_{\ell_i}}(x)$ with $t_{\ell_i} \geq 0$. Suppose that $n_x(t)$ admits a minimum value, then consider the least $\ell$ such that $n_x(t_{\ell_i})$ is equal to this minimum. Then, $r(x_{\ell_i}') > 2$ and $\rho_x(t_{\ell_i}) \geq 0$ for all $t \geq 0$ and by Proposition 6.3 the $K$-orbit of $x$ escapes.

Hence, there is an infinite sequence $t_{\ell_0} < t_{\ell_1} < \cdots$ where $\ell_i$ is the least index with $n_x(t_{\ell_i}) = -i$, and all $x_{\ell_i}$ must be secondary exit points. We claim that $r(x_{\ell_i}') > r(x_{\ell_{i+1}}') > 2$ for all $i$. Observe that $r(x_{\ell_i}') \geq r(x_{\ell_0}')$ for all $\ell_0 \leq \ell < \ell_1$ and $r(x_{\ell_{i-1}}') = r(x_{\ell_0}')$ by Proposition 5.5 so that $2 < r(x_{\ell_i}') < r(x_{\ell_{i-1}}') = r(x_{\ell_0}')$ by the Radius Inequality.

Continue in this way, to obtain a sequence of points $x_{\ell_i}$ for which

$$2 < \cdots < r(x_{\ell_{i+1}}') < r(x_{\ell_i}') < \cdots < r(x_{\ell_0}') < r(x_{\ell_{i-1}}').$$

It follows that $\lim_{i \to \infty} \{r(x_{\ell_{i+1}}') - r(x_{\ell_i}')\} = 0$ and $\lim_{i \to \infty} r(x_{\ell_i}') = r_* \geq 2$. The Radius Inequality implies that for each $j = 1, 2$, there is a unique fixed point for the radius coordinate on the range and domain of the inverse $\sigma_j^{-1}$ of the insertion map, which is the point $r = 2$ and $z = (-1)^j$. Thus, $\lim_{i \to \infty} r(x_{\ell_i}) = 2$ and there is a subsequence of this subsequence converging to one of the special points. \hfill $\square$

**Corollary 7.10.** Suppose that the $K$-orbit of $x \in K$ is forward trapped, then there is a sequence of times $0 < t_1 < t_2 < \cdots$ such that $\rho_x(t_i) \to 2$ and $z(\Phi_{t_i}(x)) \to \pm 1$. The analogous conclusion holds when the $K$-orbit of $x \in K$ is backward trapped.

Proof. Assume that the $K$-orbit of $x$ is forward trapped.

If $\rho_x(t) > 2$ for $t \geq 0$, then the claims follow from Proposition 7.9.

If $\rho_x(t) = 2$ for some $t \geq 0$, then the claims follow from Proposition 7.1.

If $r(x) < 2$ and $\rho_x(t) \neq 2$ for $t \geq 0$ then the claims follow from Proposition 7.6.

If the $K$-orbit of $x \in K$ is backward trapped, consider the reverse $K$-orbit to obtain the claims. \hfill $\square$
8. THE KUPERBERG MINIMAL SET

In this section, we give the proof that the flow $\Phi_t$ has no periodic orbits in the plug $\mathbb{K}$, and then discuss some of the properties of the minimal set $\Sigma$ for the flow. We also state some results on the non-wandering set of the flow.

**THEOREM 8.1.** The flow $\Phi_t$ in the Kuperberg Plug is aperiodic.

**Proof.** Suppose there exist a periodic orbit $x \in \mathbb{K}$ for the flow $\Phi_t$. We show that this leads to a contradiction.

Let $x_t = \Phi_t(x) = \Phi_t(x_0)$ with $0 \leq t_0 < t_1 < \cdots < t_n < \cdots$ be the forward transition points in $\{\Phi_t(x) \mid t \geq 0\}$ and suppose that $x_n$ is the first transition point with $x_n = \Phi_{t_n}(x_0) = x_0$ for $t_n > 0$. Note that we then have $\Phi_{t+t_n}(x) = \Phi_t(x)$ for all $t$.

Let $[x'_\ell, y'_{\ell+1}]_W \subset \mathbb{W}$ be the lift of the $W$-arc $[x_\ell, x_{\ell+1}]_K \subset \mathbb{K}$ for $0 \leq \ell < n$. Then $[x'_\ell, y'_{\ell+1}]_W = [x'_\ell, y'_{\ell+1}]_W$. Recall that the $r$-coordinate is constant on each $W$-arc $[x'_\ell, y'_{\ell+1}]_W$ and define $r_0 = \min\{r([x'_\ell, y'_{\ell+1}]_W) \mid 0 \leq \ell < n\}$. We may assume this minimum occurs for $[x'_0, y'_{1}]_W$.

If $r([x'_\ell, y'_{\ell+1}]_W) = 2$ for some $0 \leq \ell < n$, then the $K$-orbit of $x_t$ is either trapped or infinite by Proposition 7.1. The same is true for $x$, which contradicts the assumption that $x$ is a periodic point. Thus $r(x'_\ell) \neq 2$ for all $\ell$. If $r([x'_\ell, y'_{\ell+1}]_W) < 2$ for some $0 \leq \ell < n$, then by Proposition 7.6 the orbit of $x$ contains a special orbit in its closure, which contradicts the assumption that the orbit is periodic. Thus $r_0 > 2$.

As $r([x'_0, y'_{1}]_W) \geq r_0 > 2$, we have that $r(x'_0) > r(y'_1)$ and then Condition (K8) implies that $x_1$ must be a secondary entry point. Thus, $n_{x_0}(t_1) = 1$.

Next, observe that if $n_{x_0}(t) < 0$ for some $t > 0$, then there is a least $\ell > 0$ such that $n_{x_0}(t_\ell) < 0$. Hence $n_{x_0}(t_{\ell-1}) = 0$, and both $x_{\ell-1}$ and $x_\ell$ are secondary exit points by the minimality of $\ell$. Then by Proposition 5.5 we have $x'_0 \prec_W y'_0$. Thus $r(x'_0) = r(x'_0) = r_0$. As $r(x'_\ell) \neq 2$ and $x_\ell$ is a secondary exit point, it follows that $r(x'_\ell) < r(x'_{\ell-1}) = r_0$, which is a contradiction. Thus, we have $n_{x_0}(t) \geq 0$ for all $t > 0$.

Next, suppose that $n_{x_0}(t_n) = 0$, we can then apply Proposition 5.5 to the orbit segment $[x_0, x_{n+1}]_K$ to conclude that $x'_0 \prec_W y'_{n+1}$. Hence, $x'_0 \prec_W y'_1 \prec_W x'_n \prec_W y'_{n+1}$, but since $x_0 = x_n$ we conclude $x'_0 \prec_W y'_1 \prec_W x'_0$. Hence, the $W$-arc $[x'_0, y'_1]$ is contained in one of the $W$-periodic orbits, in particular $r(x_0) = 2$ which is a contradiction.

The only possibility left is that $n_{x_0}(t_n) > 0$, but this is impossible by considering the reversed flow and then it becomes the forbidden case $n_{x_0}(t_n) < 0$ considered above.

The above proof is essentially that given by Kuperberg in [27]. Proposition 5.5 is not formally stated in her paper, though it is stated explicitly in the subsequent treatments [17, 28, 34].

We now give a summary of general properties of the minimal set for the Kuperberg flow, as observed in [17, 28, 34]. These are based on Theorem 8.1 and results of previous sections. Recall that $p^-_i = \tau(L^-_i \cap O_i)$ for $i = 1, 2$ are the special entry points. Define the orbit closures in $\mathbb{K}$,

$$
\Sigma_1 \equiv \{\Phi_t(p^-_1) \mid -\infty < t < \infty\}, \quad \Sigma_2 \equiv \{\Phi_t(p^-_2) \mid -\infty < t < \infty\}.
$$

**THEOREM 8.2.** For the closed sets $\Sigma_i$ for $i = 1, 2$ we have:

1. $\Sigma_i$ is $\Phi_t$-invariant;
2. $r(x) \geq 2$ for all $x \in \Sigma_i$;
3. $\Sigma_1 = \Sigma_2$ and we set $\Sigma = \Sigma_1 = \Sigma_2$;
4. $\Sigma \subset Z$, where $Z \subset \mathbb{K}$ is any closed invariant set for $\Phi_t$;
5. $\Sigma$ is the unique minimal set for $\Phi_t$;

**Proof.** For 1) note that the closure of any $\Phi_t$-orbit is a $\Phi_t$-invariant set.

For 2) note that for any point $x \in r(O_1 \cap \mathbb{W})$, Corollary 7.2 shows that $n_{x_0}(t) \geq 0$ for all $t \geq 0$, hence $\rho_x(t) \geq r(x) = 2$. Thus all points $y \in \Sigma_i$ in the closure of the orbit also satisfy $r(y) \geq 2$. 

For 3) first observe that the proof of Proposition 7.1 for $p_1$ implies that $\Sigma_1$ contains $p_2^-$, and thus $\Sigma_2 \subset \Sigma_1$. It likewise implies that $\Sigma_1 \subset \Sigma_2$, and thus $\Sigma_1 = \Sigma_2$.

For 4) let $x \in Z$ then $Z$ is invariant implies that $x$ has an infinite orbit. By Theorem 8.1 the orbit of $x$ is not periodic.

If $\rho_x(t) = 2$ for some $t \in \mathbb{R}$, then Proposition 7.1 shows that the $\Phi_t$-orbit of $x$ contains a special point in its closure, hence $\Sigma \subset Z$. If $r(x) < 2$ and $\rho_x(t) \neq 2$ for all $t \in \mathbb{R}$, then Proposition 7.6 shows that the $\Phi_t$-orbit of $x$ contains a special point in its closure, hence $\Sigma \subset Z$. If $r(x) > 2$ and $\rho_x(t) \leq 2$ for some $t$, then we are reduced to the above cases. Otherwise, if $\rho_x(t) > 2$ for all $t$, then Proposition 7.9 shows that the $\Phi_t$-orbit of $x$ again contains a special point in its closure. Thus, in all cases, the closure of an infinite orbit must contain $\Sigma$ in its closure.

For 5) note that the closure of the $\Phi_t$-orbit of any $x \in \Sigma$ contains $\Sigma$, so the set is minimal. Suppose that $Z$ is a minimal set for $\Phi_t$ then given any $x \in Z$, by 4) we have $\Sigma \subset Z$, so they must be equal.

We conclude this discussion of the Kuperberg minimal set, with some observations concerning other aspects of the topological dynamics of a Kuperberg flow, which follow from the results of the previous sections. Recall that the orbits of the Kuperberg flow are divided into those which are finite, forward or backward trapped, or trapped in both directions and so infinite. Correspondingly, the asymptotic properties of the orbits must be considered within this restraint, as the asymptotic behavior outside of the plug $K$ of an orbit which escapes is not known.

First, we recall some standard definitions from topological dynamics. The forward limit set of a forward trapped point $x \in K$ is the $\Phi_t$-invariant set

\begin{equation}
\alpha(x) = \bigcap_{T \to -\infty} \{ \Phi_t(x) \mid t \geq T \},
\end{equation}

and $x$ is forward recurrent if $x \in \alpha(x)$. The backward limit set of a backward trapped point $x \in K$ is the $\Phi_t$-invariant set

\begin{equation}
\omega(x) = \bigcap_{T \to -\infty} \{ \Phi_t(x) \mid t \leq T \}
\end{equation}

and $x$ is backward recurrent if $x \in \omega(x)$.

**Corollary 8.3.** Let $x$ be forward trapped, then $\Sigma \subset \alpha(x)$. Likewise, if $x$ is backward trapped, then $\Sigma \subset \omega(x)$.

**Proof.** Theorem 8.2.4 yields the inclusions $\Sigma \subset \alpha(x)$ and $\Sigma \subset \omega(x)$. □

Next, consider the opposite extreme from recurrent points. A point $x \in K$ is forward wandering if there exists an open set $x \in U \subset K$ and $T_U > 0$ so that for all $t \geq T_U$ we have $\Phi_t(U) \cap U = \emptyset$. Similarly, $x$ is backward wandering if there exists an open set $x \in U \subset K$ and $T_U < 0$ so that for all $t \leq T_U$ we have $\Phi_t(U) \cap U = \emptyset$. A point $x$ with infinite orbit is wandering if it is forward and backward wandering.

Define the following subsets of $K$:

\begin{align*}
\mathcal{W}^0 & \equiv \{ x \in K \mid x \text{ orbit is finite} \} \\
\mathcal{W}^+ & \equiv \{ x \in K \mid x \text{ orbit is forward wandering} \} \\
\mathcal{W}^- & \equiv \{ x \in K \mid x \text{ orbit is backward wandering} \} \\
\mathcal{W}^\infty & \equiv \{ x \in K \mid x \text{ is wandering} \}
\end{align*}

Note that $x \in \mathcal{W}^0$ if and only if the orbit of $x$ escapes through $\partial^+_h K$ in forward time, and escapes though $\partial^-_h K$ in backward time. Define

\begin{equation}
\mathcal{W} = \mathcal{W}^0 \cup \mathcal{W}^+ \cup \mathcal{W}^- \cup \mathcal{W}^\infty; \quad \Omega = K - \mathcal{W}.
\end{equation}
The set $\Omega$ is called the non-wandering set for $\Phi_t$. A point $x$ with forward trapped orbit is characterized by the property: $x \in \Omega$ if for all $\epsilon > 0$ and $T > 0$, there exists $y$ and $t > T$ such that $d(x, y) < \epsilon$ and $d(x, \Phi_t(y)) < \epsilon$, where $d(x, y)$ is a distance function defined in Section 4. There are obvious corresponding statements for points which are backward trapped or infinite.

We now give some of the properties of the wandering and non-wandering sets.

**Lemma 8.4.** $\Omega$ is a closed, $\Phi_t$-invariant subset, with $\Sigma \subset \Omega$.

**Proof.** The fact that each of the sets $\mathcal{M}^0$, $\mathcal{M}^+$, $\mathcal{M}^-$ and $\mathcal{M}^\infty$ is open follows directly from the definition of wandering, as does their invariance under the flow $\Phi_t$. For $x \in \Sigma$, its orbit is recurrent so is not wandering, hence $x \in \Omega$. □

**Lemma 8.5.** If $x \in K$ is a primary entry or exit point, then $x \in \mathcal{M}$.

**Proof.** Let $x \in \partial^-_h K$ be a primary entry point. Then for some $\epsilon > 0$, the choice of the vector field $\mathcal{W}$ on $\mathcal{W}$ implies that the coordinate function $z(\Phi_t(z))$ is strictly increasing for $0 \leq t \leq \epsilon$. For $0 < \delta < \epsilon$, let $B(x, \delta)$ be the closed ball of radius $\delta$ centered at $x$. Then for $\delta$ sufficiently small, the image $\Phi_t(B(x, \delta))$ is disjoint from $B(x, \delta)$ for all $t > \epsilon$. Thus, $x \in \mathcal{M}^0$ if its orbit is not trapped and $x \in \mathcal{M}^+$ if its orbit is trapped. Similar considerations apply for a primary exit point $x \in \partial^+_h K$, to show that either $x \in \mathcal{M}^0$ or $x \in \mathcal{M}^-$. □

**Corollary 8.6.** For each $x \in \Omega$, the $\Phi_t$-orbit of $x$ is infinite.

We can also restrict the radius coordinates of the non-wandering orbits.

**Proposition 8.7.** $\Omega \subset \{x \in K \mid r(x) \geq 2\}$.

**Proof.** Let $x \in \Omega$ and suppose that $r(x) = r_0 < 2$. Note that $x$ is an infinite orbit implies that $r(x) > 1$ and $x$ cannot be contained in the orbit of a special point as $r(x) < 2$. Moreover, it follows as in the proof of Lemma 7.7 that the level function $n_x(t)$ has a greatest lower bound $N_x \leq 0$ for all $t \in \mathbb{R}$. Let $x_\ast = \Phi_{t_\ast}(x)$ be a transition point with $n_{x_\ast}(t_\ast) = N_x$. As $\Omega$ is $\Phi_t$-invariant, it will suffice to show that $x_\ast$ is wandering, which is a contradiction. Thus, we may assume that $x = x_\ast$ and the level function satisfies $n_{x_\ast}(t) \geq 0$ for $t \geq 0$.

Let $x_\ell = \Phi_{t_\ell}(x)$ with $0 = t_0 < t_1 < \cdots < t_\ell < \cdots$ be the forward transition points in $\{\Phi_t(x) \mid t \geq 0\}$. Let $[x_\ell, y_{\ell+1}]_K \subset \mathbb{W}$ be the lift of the $\mathcal{W}$-arc $[x_\ell, x_{\ell+1}]_K$, for $\ell \geq 0$.

The proof of Proposition 7.6 shows that there are only a finite number of indices $\ell \geq 0$ such that $x_\ell$ is a transition point with level $n_{x_\ell}(t_\ell) = 0$. Let $\ell_0 \geq 1$ be the greatest index for which $n_{x}(t_{\ell_0} - 1) = 0$. Then $n_{x}(t_{\ell}) \geq 1$ for all $\ell \geq \ell_0$, which implies that both $x_{\ell_0}$ and $x_{\ell_0+1}$ are secondary entry points and thus $x_{\ell_0}' \in L^-_t$ for $i = 1$ or $i = 2$ and $y_{\ell_0+1}' \in L^-_j$ for $j = 1$ or $j = 2$.

We have $r_0 = r(x_0') = r(x_{\ell_0-1}')$ and set $r_1 = r(x_{\ell_0}')$. As $x$ is not on a special orbit, the Radius Inequality (K8) implies that $r_1 > r_0$. By the geometry of the insertion maps $\sigma_j$, it follows that $x_{\ell_0}' \in L^-_t$ must be an interior point for the compact region $L^-_t$. The flow $\Phi_t$ is transverse to the section $T_K$ defined in [10], so it follows that there exists $\delta_0 > 0$ such that, for each $0 \leq \ell \leq \ell_0$, the ball $B(x_\ell, \delta_0)$ intersects just one component of $T_K$ and is disjoint from its boundary.

By the continuity of the flow, we can choose $0 < \epsilon \leq \delta_0$ sufficiently small so that $\Phi_{t_\ell}(B(x, \epsilon)) \subset B(x_\ell, \delta_0)$ for each $0 \leq \ell \leq \ell_0$. Moreover, for $r_0' = r_0 + (r_1 - r_0)/3$ and $r_1' = r_1 - (r_1 - r_0)/3$ we require that $r(y) \leq r_0'$ for each $y \in B(x, \epsilon) \cap T_K$ and $r(z) \geq r_1'$ for each $z \in B(x_\ell, \delta_0) \cap T_K$.

For $y \in B(x, \epsilon)$, it then follows that for each $0 \leq \ell \leq \ell_0$, $\Phi_{t_\ell}(y)$ is an interior point of $T_K$ for some $t_\ell'$ close to $t_\ell$. In particular, $\Phi_{t_\ell}(y)$ is a secondary entry point with $n_{y_{t_\ell}}(t_{\ell}') = n_{x}(t_{\ell_0}) = 1$. As in the proof of Proposition 7.6 it follows that $n_{y_{t_\ell}}(t) \geq 1$ for all $t \geq t_{\ell_0}$ and $r(\Phi_{t_\ell}(y)) \geq r(\Phi_{t_{\ell_0}}(y)) \geq r_1'$ for all $t \geq t_{\ell_0}$. Thus, $\Phi_{t_\ell}(B(x, \epsilon)) \cap B(x, \epsilon) = \emptyset$ for all $t \geq t_{\ell_0}$, so that $x$ is forward wandering, as was to be shown. □
9. The Kuperberg pseudogroup

In this section, we define a pseudogroup $G_K$ acting on a rectangle $R_0 \subset K$ which captures the dynamics of the flow $\Phi_t$. The study of the action of $G_K$ leads to a deeper understanding of the geometry and topology of the minimal set $\Sigma$, and gives a framework for the rest of the paper. The analysis of the dynamical properties of the action of $G_K$ on $R_0$ uses many of the results and techniques developed in the previous sections and provides an interpretation of these results in a pseudogroup setting.

Choose a value of $\theta_0$ such that the rectangle $R_0$ as defined in cylindrical coordinates,

\[ R_0 \equiv \{ \xi = (r, \theta_0, z) \mid 1 \leq r \leq 3, -2 \leq z \leq 2 \} \subset \mathbb{W}', \]

is disjoint from both the regions $D_i$ and their insertions $D_i$ for $i = 1, 2$, as defined in Section 3. For example, for the curves $\alpha_i$ and $\beta'_i$ defined in Section 3, we can take $\theta_0 = \pi$, so that $R_0$ is between the embedded regions $D_i$ for $i = 1, 2$ as illustrated in Figure 16.

**Figure 16.** The rectangle $R_0$ in the Kuperberg plug $K$

As $R_0 \subset \mathbb{W}'$, the quotient map $\tau: \mathbb{W} \to K$ is injective on $R_0$ and we denote its image in $K$ also by $R_0$ with coordinates $r = r(\xi)$ and $z = z(\xi)$ for $\xi \in R_0$. The metric on $R_0$ is given by

\[ d_{R_0}(\xi, \xi') = \sqrt{(r' - r)^2 + (z' - z)^2} \quad \text{for} \quad \xi = (r, \pi, z), \quad \xi' = (r', \pi, z'). \]

Introduce the special points $\omega_i \in R_0$, given by

\[ \omega_1 = \mathcal{O}_1 \cap R_0 = (2, \pi, -1), \quad \omega_2 = \mathcal{O}_2 \cap R_0 = (2, \pi, 1). \]

The first transition point of the forward orbit of $\omega_i$ is the special entry point $p^-_i = \tau(\mathcal{L}^-_i \cap \mathcal{O}_i) \in E_i$. The first transition point of the backward orbit of $\omega_i$ is the special exit point $p^+_i = \tau(\mathcal{L}^+_i \cap \mathcal{O}_i) \in S_i$.

We next give a basic result concerning the behavior of $K$-orbits with respect to $R_0$.

**Proposition 9.1.** Let $x \in K$ be such that its forward (or backward) $K$-orbit is trapped, then the orbit intersects $R_0$. Hence, if the $K$-orbit of $x$ does not intersect $R_0$, it escapes from $K$ in both forward and backward time.

**Proof.** Both the forward and the backward $K$-orbit of a special point $p^-_i$ limits to each special point $p^+_j$ by Proposition 7.4 and thus intersects $R_0$ repeatedly. It follows that there is an open neighborhood of each of the special points $\{\omega_1, \omega_2\}$ consisting of points whose forward and backward $K$-orbit intersects $R_0$. Suppose that $r(x) < 2$, then by Proposition 7.6 the assumption that the forward orbit of $x$ is trapped implies that it contains a special point in its closure, hence must intersect $R_0$ infinitely often. The case where $r(x) \geq 2$ follows.
similarly by Propositions \[7.1\] and \[7.9\]. The case when the backward orbit is trapped follows by reversing the flow and applying the above case. \[\square\]

**COROLLARY 9.2.** If \( x \in \mathbb{K} \) belongs to an infinite \( \mathcal{K} \)-orbit, then it intersects \( \mathbf{R}_0 \) in an infinite sequence of points in both forward and backward time. \[\square\]

The first return map \( \hat{\Phi} \) on \( \mathbf{R}_0 \) for the Kuperberg flow \( \Phi_t \) is defined at \( \xi \in \mathbf{R}_0 \) if there is a \( \mathcal{K} \)-orbit segment \([\xi, \eta)_\mathcal{K} \) with \( \eta \in \mathbf{R}_0 \) and its interior \((\xi, \eta)_\mathcal{K} \) is disjoint from \( \mathbf{R}_0 \). We then set \( \hat{\Phi}(\xi) = \eta \). The domain of \( \hat{\Phi} \) is the set:

\[
\text{Dom}(\hat{\Phi}) = \{ \xi \in \mathbf{R}_0 \mid \exists \; t > 0 \text{ such that } \Phi_t(\xi) \in \mathbf{R}_0 \text{ and } \Phi_s(\xi) \notin \mathbf{R}_0 \text{ for } 0 < s < t \}.
\]

Corollary 9.2 implies that every \( x \in \mathbf{R}_0 \) with infinite orbit is in the domain of \( \hat{\Phi} \), and thus the dynamical behavior of the map \( \hat{\Phi} \) reflects the dynamical behavior of the infinite orbits for \( \Phi_t \). We also note that the map \( \hat{\Phi} : \text{Dom}(\hat{\Phi}) \rightarrow \mathbf{R}_0 \) has many points of discontinuity, as will be shown.

Recall the formal definition of a pseudogroup modeled on a space \( X \):

**DEFINITION 9.3.** A pseudogroup \( \mathcal{G} \) modeled on a topological space \( X \) is a collection of homeomorphisms between open subsets of \( X \) satisfying the following properties:

1. For every open set \( U \subset X \), the identity \( \text{Id}_U : U \rightarrow U \) is in \( \mathcal{G} \).
2. For every \( \varphi \in \mathcal{G} \) with \( \varphi : U_\varphi \rightarrow V_\varphi \) where \( U_\varphi, V_\varphi \subset X \) are open subsets of \( X \), then also \( \varphi^{-1} : V_\varphi \rightarrow U_\varphi \) is in \( \mathcal{G} \).
3. For every \( \varphi \in \mathcal{G} \) with \( \varphi : U_\varphi \rightarrow V_\varphi \) and each open subset \( U' \subset U_\varphi \), then the restriction \( \varphi | U' \) is in \( \mathcal{G} \).
4. For every \( \varphi \in \mathcal{G} \) with \( \varphi : U_\varphi \rightarrow V_\varphi \) and every \( \varphi' \in \mathcal{G} \) with \( \varphi' : U_{\varphi'} \rightarrow V_{\varphi'} \), if \( V_{\varphi'} \subset U_{\varphi'} \) then the composition \( \varphi' \circ \varphi \) is in \( \mathcal{G} \).
5. If \( U \subset X \) is an open set, \( \{ U_\alpha \subset X \mid \alpha \in \mathcal{A} \} \) are open sets whose union is \( U \), \( \varphi : U \rightarrow V \) is a homeomorphism to an open set \( V \subset X \) and for each \( \alpha \in \mathcal{A} \) we have \( \varphi_\alpha = \varphi | U_\alpha : U_\alpha \rightarrow V_\alpha \) is in \( \mathcal{G} \), then \( \varphi \) is in \( \mathcal{G} \).

We apply this definition to the first return map \( \hat{\Phi} \) on \( \mathbf{R}_0 \) to obtain:

**DEFINITION 9.4.** Let \( \mathcal{G}_\mathcal{K} \) be the pseudogroup generated by the map \( \hat{\Phi} \) acting on \( X = \mathbf{R}_0 \). That is, if \( U \subset \text{Dom}(\hat{\Phi}) \) is an open set with \( V = \hat{\Phi}(U) \) and the restriction \( \hat{\Phi} | U \) is a homeomorphism, then both \( \hat{\Phi}|U \) and \( \hat{\Phi}^{-1}|V \) are in \( \mathcal{G}_\mathcal{K} \). The remaining elements of \( \mathcal{G}_\mathcal{K} \) are given by adding maps as required so that the conditions of Definition 9.3 are satisfied.

In the rest of this section, we consider the basic dynamical properties of the action of \( \mathcal{G}_\mathcal{K} \) on \( \mathbf{R}_0 \) and begin developing the relationship between the dynamics of the flow \( \Phi_t \) on \( \mathbb{K} \) and that of the induced action of \( \hat{\Phi} \). We first consider the relation between the actions of the maps \( \hat{\Phi} \) and \( \tilde{\Psi} \) on \( \mathbf{R}_0 \), where \( \tilde{\Psi} \) denotes the return map to \( \mathbf{R}_0 \) for the Wilson flow \( \Psi_t \). The dynamical properties of \( \Psi_t \) on \( \mathcal{W} \) are described in Proposition 2.1 and illustrated in Figures 2 and 3.

The first return map \( \tilde{\Psi} \) on \( \mathbf{R}_0 \) for the Wilson flow \( \Psi_t \) is defined at \( \xi \in \mathbf{R}_0 \) if there is a \( \mathcal{W} \)-orbit segment \([\xi, \eta]_\mathcal{W} \) with \( \eta \in \mathbf{R}_0 \) and its interior \((\xi, \eta)_\mathcal{W} \) is disjoint from \( \mathbf{R}_0 \). We then set \( \tilde{\Psi}(\xi) = \eta \). The domain of \( \tilde{\Psi} \) is the set:

\[
\text{Dom}(\tilde{\Psi}) = \{ \xi \in \mathbf{R}_0 \mid \exists \; t > 0 \text{ such that } \Psi_t(\xi) \in \mathbf{R}_0 \text{ and } \Psi_s(\xi) \notin \mathbf{R}_0 \text{ for } 0 < s < t \}.
\]

The radius function is constant along the orbits of the Wilson flow, so that \( r(\tilde{\Psi}(\xi)) = r(\xi) \) for all \( \xi \in \text{Dom}(\tilde{\Psi}) \). Also, note that the points \( \omega_i \) for \( i = 1, 2 \) defined in (27) are fixed-points for \( \tilde{\Psi} \). For all other points \( \xi \in \mathbf{R}_0 \) with \( \xi \neq \omega_i \), it was assumed in Section 2 that the function \( g(r, \theta, z) > 0 \), so the \( \mathcal{W} \)-orbit of \( \xi \) has a “vertical drift” arising from the term \( g(r, \theta, z) \frac{\partial}{\partial z} \) in the formula (3) for \( \mathcal{W} \).

For \( \xi \in \mathbf{R}_0 \) sufficiently close to the vertical boundary \( \partial_\mathcal{W} \), function \( f(r, \theta, z) = 0 \) and hence the vector field \( \mathcal{W} \) is tangent to \( \mathbf{R}_0 \). Then the \( \Psi_t \)-flow of \( \xi \) is contained in \( \mathbf{R}_0 \) and hence \( \xi \notin \text{Dom}(\tilde{\Psi}) \).
For \( \xi \in \mathbf{R}_0 \) such that \( \mathcal{W} \) is not vertical at \( \xi \), then the \( \Psi_t \)-flow of \( \xi \) exits \( \mathbf{R}_0 \) and has increasing \( z \)-coordinate, and so flows upward until it either returns to \( \mathbf{R}_0 \), or exits through \( \partial^+_h \mathcal{W} \) without intersecting \( \mathbf{R}_0 \), in which case it fails to make a complete revolution around the cylinder. In the latter case, \( \xi \notin \text{Dom}(\hat{\Psi}) \). If \( z(\xi) \geq 0 \), then whether its forward \( \Psi_t \)-flow returns to \( \mathbf{R}_0 \) or not, depends strongly on the choices of the functions \( g(r, \theta, z) \) and \( f(r, \theta, z) \) and the minimum distance from the forward orbit of \( \xi \) to the fixed-point \( \omega_2 \).

On the other hand, let \( \xi = (r, \pi, z) \in \mathbf{R}_0 \) with \( z < 0 \) and suppose that \( \mathcal{W} \) is not vertical at \( \xi \). Then as before, the forward \( \Psi_t \)-orbit of \( \xi \) exits \( \mathbf{R}_0 \) and has increasing \( z \)-coordinate, so must intersect the annular region \( \mathcal{A} = \{z = 0\} \). If the forward orbit does not intersect \( \mathbf{R}_0 \) before crossing \( \mathcal{A} \), then by the anti-symmetry hypothesis on the Wilson flow, the \( \Psi_t \)-orbit of \( \xi \) returns to \( \mathbf{R}_0 \) at the point \( \eta = (r, \pi, -z) \), and so \( \hat{\Psi}(\xi) = \eta \).

Note that these remarks imply that for all \( \xi \in \mathbf{R}_0 \) with \( z(\xi) < 0 \) and such that \( \mathcal{W} \) is not vertical at \( \xi \), then \( \xi \in \text{Dom}(\hat{\Psi}) \). However, which of the two cases above occurs again depends strongly on the choices of the functions \( g(r, \theta, z) \) and \( f(r, \theta, z) \) and the minimum distance from the forward orbit of \( \xi \) to the fixed-points \( \omega_i \).

Finally, we consider the domain of \( \hat{\Psi} \) in an open neighborhood of the vertical segment \( \{r = 2\} \). For \( \xi \in \mathbf{R}_0 \) sufficiently close to one of the fixed points \( \omega_i \), the function \( g(r, \theta, z) \) is arbitrarily small, so the forward \( \mathcal{W} \)-orbit of \( \xi \) must intersect \( \mathbf{R}_0 \), and thus \( \xi \in \text{Dom}(\hat{\Psi}) \). In particular, for each \( \omega_i \) the set \( \text{Dom}(\hat{\Psi}) \) contains a open neighborhood of \( \omega_i \). The return map for \( \hat{\Psi} \) at other points close to \( \{r = 2\} \) is considered in three cases, which are illustrated in Figures 2 and 3.

First, the \( \Psi_t \)-flow of the points in the open segment

\[
\mathcal{I}_0 = \{(2, \pi, z) \mid -1 < z < 1\} \subset \{r = 2\} \cap \mathbf{R}_0
\]

always return to the same segment, so we have \( \mathcal{I}_0 \subset \text{Dom}(\hat{\Psi}) \) with \( \hat{\Psi} : \mathcal{I}_0 \to \mathcal{I}_0 \). Moreover, \( \hat{\Psi} \) is bijective when restricted to \( \mathcal{I}_0 \). However, \( \hat{\Psi} \) is not continuous on \( \mathcal{I}_0 \) as we will discuss further below.

The conditions (W5) and (W6) in Section 2 imply there exists a least \( 0 < \epsilon_f < 1/4 \) such that the function \( f(2, \theta, z) > 0 \) for \( -2 + \epsilon_f < z < 0 \). Thus, for the open segment

\[
\mathcal{J}_0 = \{(2, \pi, z) \mid -2 + \epsilon_f \leq z < -1\} \subset \{r = 2\} \cap \mathbf{R}_0
\]

we have \( \mathcal{J}_0 \subset \text{Dom}(\hat{\Psi}) \) and \( \hat{\Psi}(\mathcal{J}_0) \subset \mathcal{J}_0 \). By the anti-symmetry condition (W1) for the function \( f \), we also have that \( f(2, \theta, z) < 0 \) for \( 0 < z < 2 - \epsilon_f \). Thus, for the open segment

\[
\mathcal{K}_0 = \{(2, \pi, z) \mid 1 < z \leq 2 - \epsilon_f\} \subset \{r = 2\} \cap \mathbf{R}_0
\]

we have \( \mathcal{K}_0 \subset \text{Dom}(\hat{\Psi}^{-1}) \) and \( \hat{\Psi}^{-1}(\mathcal{K}_0) \subset \mathcal{K}_0 \). Therefore, \( \mathcal{I}_0, \mathcal{J}_0 \) and \( \hat{\Psi}^{-1}(\mathcal{K}_0) \) are in the interior of \( \text{Dom}(\hat{\Psi}) \).

In order to illustrate the regions in the domain of \( \hat{\Psi} \) as described above, assume that \( 0 \leq g(r, \theta, z) \leq 1/10 \) and that \( g(r, \theta, z) = 1/10 \) when allowed. Thus, the flow of \( \Psi_t \) rises at an approximate rate of \( 1/10 \) in \( \mathcal{W} \), and \( z(\hat{\Psi}(\xi)) \approx z(\xi) + r(\xi)/10 \). Figure 17(A) pictures the three regions of the domain in this case.

We next consider the continuity properties of the return map \( \hat{\Psi} \). Recall that the Wilson flow reverses direction at the annulus \( \mathcal{A} = \{z = 0\} \subset \mathcal{W} \), and is anti-symmetric with respect to the annulus \( \mathcal{A} \) by Condition (W1) in Section 2 so that \( \mathcal{W} \) is tangent to \( \mathbf{R}_0 \) along the line \( \mathcal{T} = \mathcal{A} \cap \mathbf{R}_0 \).

Let \( \xi = (r, \pi, z) \in \text{Dom}(\hat{\Psi}) \) and \( \eta = \hat{\Psi}(\xi) = (r, \pi, 0) \). Then there exists a \( \mathcal{W} \)-orbit segment \( [\xi, \eta]_\mathcal{W} \) which intersects \( \mathbf{R}_0 \) only in its endpoints, and the \( \Psi_t \)-flow of \( \xi \) is tangent to \( \mathbf{R}_0 \) at \( \eta \in \mathcal{T} \). Let \( \xi' = (r, \pi, z') \) with \( z - \epsilon' < z' < z \), for \( \epsilon' > 0 \) sufficiently small, then \( \eta' = \hat{\Psi}(\xi') \) is defined and satisfies \( z(\hat{\Psi}(\xi')) < 0 \), with value depending continuously on \( z' \). On the other hand, for \( \xi'' = (r, \pi, z'') \) with \( z < z'' < z + \epsilon'' \), for \( \epsilon'' > 0 \) sufficiently small, then the point \( \eta'' = \hat{\Psi}(\xi'') \) is again well-defined. But the \( \mathcal{W} \)-orbit segment \( [\xi'', \eta'']_\mathcal{W} \) is no longer tangent to \( \mathbf{R}_0 \) near \( \eta \), as it traverses \( \mathcal{W} \) in a counter-clockwise direction in the region \( \{z < 0\} \), until it crosses the plane \( \{z = 0\} \) before reaching the surface \( \mathbf{R}_0 \), and then afterwards reverses direction and subsequently intersects \( \mathbf{R}_0 \) from the opposite direction in the region \( \{z > 0\} \), at a point close to \( \hat{\Psi}^2(\xi) \). Consequently, the map \( \hat{\Psi} \) has a discontinuity at \( \xi \), and so \( \mathcal{L}_1 = \hat{\Psi}^{-1}(\mathcal{T}) \) is a curve of discontinuities for \( \hat{\Psi} \).
There is another type of discontinuity for $\hat{\Psi}$ that arises for $\xi = (r, \pi, 0) \in \mathcal{T}$. For $\epsilon' > 0$ sufficiently small, then for $\xi' = (r, \pi, -z')$ with $0 < z' < \epsilon'$, we have $\hat{\Psi}(\xi') = (r, \pi, z')$ due to the anti-symmetry of $\Psi$. On the other hand, for $\xi'' = (r, \pi, z'')$ with $0 < z'' < \epsilon'$, suppose that $\eta'' = \hat{\Psi}(\xi'')$ is well-defined then the $W$-orbit segment $[\xi'', \eta'']_W$ traverses $W$ in a clockwise direction in the region $\{z > 0\}$, and so the value $z(\hat{\Psi}(\xi''))$ is much larger than 0. Thus, $\mathcal{T} \cap \text{Dom}(\hat{\Psi})$ is a set of discontinuities for $\hat{\Psi}$.

Define the three domains of continuity for the induced return map $\hat{\Psi}$ on $R_0$, as illustrated in Figure 17(A).

$$D(\hat{\Psi})^- = \{\xi \in \text{Dom}(\hat{\Psi}) \mid z(\xi) < 0 \text{ and } z(\hat{\Psi}(\xi)) \leq 0\}$$
$$D(\hat{\Psi})^+ = \{\xi \in \text{Dom}(\hat{\Psi}) \mid z(\xi) < 0 \text{ and } z(\hat{\Psi}(\xi)) > 0\}$$
$$D(\hat{\Psi})^\pm = \{\xi \in \text{Dom}(\hat{\Psi}) \mid z(\xi) \geq 0 \text{ and } z(\hat{\Psi}(\xi)) > 0\}$$

Restriction of the map $\hat{\Psi}$ thus yields three continuous maps with disjoint domains, denoted by

$$\hat{\Psi}_- = \hat{\Psi}|D(\hat{\Psi})^-, \hat{\Psi}_0 = \hat{\Psi}|D(\hat{\Psi})^\pm, \hat{\Psi}_+ = \hat{\Psi}|D(\hat{\Psi})^+.$$

A comparable analysis of the domains of continuity for the return map $\hat{\Phi}$ for the flow $\Phi_t$ is far more complicated, and will be postponed until Section 20 when techniques have been introduced which are sufficient for describing these domains. Our strategy here is to define a collection of special maps in $G_K$, obtained by the restriction of $\hat{\Phi}$ to particular domains of continuity, and which correspond to key aspects of the dynamics of the flow $\Phi_t$. We show that these special elements and all their compositions in $G_K$ capture all of the essential dynamical properties of the flow $\Phi_t$. We first consider elements of $G_K$ corresponding to the entry and exit dynamics of the two insertions.

For $i = 1, 2$, let $U_{\phi_i} \subset \text{Dom}(\hat{\Phi})$ be the subset of $R_0$ consisting of points $\xi \in \text{Dom}(\hat{\Phi})$ with $\eta = \hat{\Phi}(\xi)$, such that the $K$-arc $[\xi, \eta]_K$ contains a single transition point $x$, with $x \in E_i$. Note that for such $\xi$, we see from Figures 17(A) and 16(A) that its $K$-orbit exits the surface $E_i$ as the $W$-orbit of a point $x' \in L_i^-$ with $\tau(x') = x$, flowing upwards from $\partial_h W$ until it intersects $R_0$ again. If the $K$-orbit of $\xi$ enters $E_i$ but exits through $S_i$ before crossing $R_0$, then it is not considered to be in the domain $U_{\phi_i}$ as it contains more than one transition point.

Let $\phi_i^+: U_{\phi_i} \rightarrow V_{\phi_i}$ denote the element of $G_K$ defined by the restriction of $\hat{\Phi}$. As the $K$-arcs $[\xi, \eta]_K$ defining $\phi_i^+$ do not intersect $A$, the restricted map $\phi_i^+$ is continuous. The inverse map $(\phi_i^+)^{-1}: V_{\phi_i} \rightarrow U_{\phi_i}$ is also in $G_K$ for $i = 1, 2$. The sets $U_{\phi_i}^+$ and $V_{\phi_i}^+$ are sketched in the center illustration in Figure 17(B).

For $i = 1, 2$, let $U_{\phi_i}^- \subset \text{Dom}(\hat{\Phi})$ be the subset of $R_0$ consisting of points $\xi \in \text{Dom}(\hat{\Phi})$ with $\eta = \hat{\Phi}(\xi)$, such that the $K$-arc $[\xi, \eta]_K$ contains a single transition point $x$, with $x \in S_i$. Then let $\phi_i^- : U_{\phi_i}^- \rightarrow V_{\phi_i}^-$ denote the element of $G_K$ defined by the restriction of $\hat{\Phi}$. Again, as the $K$-arcs $[\xi, \eta]_K$ defining the maps $\phi_i^-$ do not intersect $A$, the restricted map $\phi_i^-$ is continuous. The inverse map $(\phi_i^-)^{-1}: V_{\phi_i}^- \rightarrow U_{\phi_i}^-$ is also in $G_K$ for $i = 1, 2$. The sets $U_{\phi_i}^-$ and $V_{\phi_i}^-$ are sketched in the right hand side illustration in Figure 17(B).

We comment on some details of the regions in Figures 17(B) and (C). For the map $\phi_i^+, i = 1, 2$, the domain contains a neighborhood of the point $\omega_i$. Flowing the domain $U_{\phi_i}^+$ forward to $E_i$ and then applying the map $\sigma_i^{-1}$ we obtain a set $\hat{U}_{\phi_i}^+ \subset L_i^-$ containing points with $r$-coordinate equal to 2. Observe that the Radius Inequality implies that the maximum radius of points in $\hat{U}_{\phi_i}^+$ is bigger than the maximum radius of points in $U_{\phi_i}^+$. The first intersection of the $W$-orbits of points in $\hat{U}_{\phi_i}^+$ with $R_0$ is thus a region containing points with $r$-coordinate equal to 2 and since these points climb slower than other points, the region folds at $\{r = 2\}$. By the choice of $R_0$, the points coming from $L_i^-$ are farther than the ones coming from $L_i^+$ and thus $V_{\phi_i}^+$ is above $V_{\phi_i}^-$. Similar considerations apply to the maps $\phi_i^-$ for $i = 1, 2$. 
Observe that each generator $\phi_i^+$ for $i = 1, 2$ corresponds to a flow through a transition point which increases the level function $n_x(t)$ by +1, so the inverse of $\phi_i^+$ decreases the level function by 1. The map $\phi_i^-$ decreases the level by −1 and its inverse increases the level by +1.

Next, we develop a relation between the action of the return map $\hat{\Psi}$ for the Wilson flow and the action of the pseudogroup $G_K$. Define subsets of $\mathbb{R}_0$ contained in the domain of the Wilson map $\hat{\Psi}$:

$U_\psi^- = \{(r, \pi, z) \in \text{Dom}(\hat{\Psi}) \mid r > 2\} \subset \mathbb{R}_0 \cap \{r > 2\}$

$R_0^- = \{(r, \pi, z) \in \text{Dom}(\hat{\Psi}) \mid r \geq 2\} \setminus \{\omega_1, \omega_2\}$

Consider $\xi, \eta \in R_0^-$ such that $\eta$ is contained in the forward $\mathcal{W}$-orbit of $\xi$, then if $r(\xi) > 2$, Propositions 6.5 and 6.7 imply that $\eta$ is in the forward $K$-orbit of $\xi$. Thus, there exists some $k > 0$ such that $\eta = \hat{\Phi}^k(\xi)$. The following result is a pseudogroup version of this observation.

**Lemma 9.5.** The continuous maps defined by restriction,

\[
\psi_- = \hat{\Psi}_- \mid \{U_\psi^- \cap D(\hat{\Psi})\} \quad , \quad \psi_0 = \hat{\Psi}_0 \mid \{U_\psi^0 \cap D(\hat{\Psi})\} \quad , \quad \psi_+ = \hat{\Psi}_+ \mid \{U_\psi^+ \cap D(\hat{\Psi})\},
\]

each belong to $G_K$ after restricting to the interiors of their domains.

**Proof.** Consider first the case of $\psi_-$. We show that for each $\xi \in U_\psi^- \cap \text{int}(D(\hat{\Psi})\})$ there is an open neighborhood $\xi \in U_\xi \subset U_\psi^- \cap \text{int}(D(\hat{\Psi})\})$ such that the restriction $\hat{\Psi} \mid U_\xi$ is in $G_K$, then the claim that $\psi_- \mid \text{int}(D(\hat{\Psi})\}) \in G_K$ follows by the gluing condition Condition 9.3.5. Let $[\xi, \eta]_\mathcal{W}$ be the $\mathcal{W}$-orbit segment from $\xi$ to $\eta = \hat{\Psi}(\xi)$.

If $[\xi, \eta]_\mathcal{W}$ contains no transition point, then it is also a $K$-orbit segment, so $\hat{\Psi}(\xi) = \hat{\Phi}(\xi)$. As the insertion regions $D_i$ are closed, the continuity of the flows implies there is an open neighborhood $U_\xi \subset U_\psi^- \cap D(\hat{\Psi})\}$ of $\xi$ such that $\hat{\Psi}|U_\xi = \hat{\Phi}|U_\xi$. By Condition 9.3.3, $\hat{\Psi}|U_\xi$ is in $G_K$. 
If \([\xi, \eta]_W \cap D_i\) is non-empty, which for this case implies \(i = 1\), then the first intersection with \(D_1\) is a point \(x' \in L^+_1\). This is followed along the \(W\)-orbit segment \([\xi, \eta]_W\) by a point \(y' \in L^+_1\) before returning to \(\eta \in R_0\). Thus, the first transition point in the \(K\)-orbit of \(\xi\) must be the secondary entry point \(x = \tau(x') \in E_1\).

As \(\xi \prec_W \eta\) with \(x \equiv y\), and \(r(\xi) > 2\) is given, Proposition 6.7 implies that \(\xi \prec_K \eta\). Moreover, from its proof we have that \(n_\xi(t) \geq 0\) for \(0 \leq t \leq t_\eta\) where \(\eta = \Phi_{t_\eta}(\xi)\), and so also \(\rho_\xi(t) \geq 2\) for \(0 \leq t \leq t_\eta\). Let \(\xi = \xi_0 \prec_K \xi_1 \prec_K \cdots \prec_K \xi_k = \eta\) be the points of intersection of \(K\)-arc \([\xi, \eta]_K\) with \(R_0\), then \(\eta = \hat{\Phi}^k(\xi)\) and \(r(\xi_\ell) > 2\) for each \(0 \leq \ell \leq k\). By the transversality of the flow \(K\) with the faces \(E_1\) and \(S_1\), it follows that there is an open neighborhood \(\xi \in U_\xi \subset U^*_\psi\) such that \(\hat{\Phi}^k|U_\xi\) is defined, and thus is the composition of elements in \(G_K\). Thus \(\hat{\Psi}|U_\xi = \hat{\Phi}^k|U_\xi \in G_K\).

The claim for the cases \(\psi_0\) and \(\psi_+\) is shown in the same way.

Next we show that the maps in \(G_K\) defined in Lemma 9.5 admit continuous extensions to open neighborhoods of the space \(R^*_0\). This technical result is fundamental for many subsequent applications of the pseudogroup approach to the study of dynamics for the flow \(\Phi_t\).

**Lemma 9.6.** There exists an open set \(U_\psi \subset R_0\) containing \(R^*_0\) such that the restrictions of \(\hat{\Psi}\) to the domains of continuity in \(U_\psi\) define elements of \(G_K\).

**Proof.** We first consider the case of the restriction \(\hat{\Psi}_\prec\{U^*_\psi \cap D(\hat{\Psi})_{\prec}\}\).

For \(\xi \in R^*_0 \cap \text{int}(D(\hat{\Psi})_{\prec})\) with \(r(\xi) > 2\), Lemma 9.5 shows there is an open neighborhood \(\xi \in U_\xi \subset U^*_\psi\) such that the restriction \(\hat{\Psi}|U_\xi\) defines an element \(\psi \in G_K\).

For \(\xi \in R^*_0 \cap \text{int}(D(\hat{\Psi})_{\prec})\) with \(r(\xi) = 2\), the return map \(\hat{\Psi}\) is defined on a sufficiently small open neighborhood of \(\xi\). Set \(\eta = \hat{\Psi}(\xi)\) and note that \(r(\eta) = 2\). Let \([\xi, \eta]_W\) be the \(W\)-orbit segment from \(\xi\) to \(\eta\). If \([\xi, \eta]_W\) contains no transition point, then this is also a \(K\)-orbit segment, so \(\hat{\Psi}(\xi) = \hat{\Phi}(\xi)\) and there is an open neighborhood \(U_\xi \subset R_0\) such that \(\hat{\Psi}|U_\xi = \hat{\Phi}|U_\xi\). Thus, \(\hat{\Psi}|U_\xi \in G_K\) defines an extension of the map \(\psi\) defined by Lemma 9.5 to the open neighborhood \(U_\xi\) of \(\xi\).

Now assume that \([\xi, \eta]_W \cap D_i\) is non-empty, and so \(i = 1\) in this case. Then the first intersection with \(D_1\) is a point \(x' \in L^+_1\). This is followed along the \(W\)-orbit segment \([\xi, \eta]_W\) by a point \(y' \in L^+_1\) before returning to \(\eta \in R_0\). Thus, the first transition point in the \(K\)-orbit of \(\xi\) must be the secondary entry point \(x = \tau(x') \in E_1\).

As \(\xi \prec_W \eta\) with \(x \equiv y\), and \(r(\xi) = 2\) is given, \(\xi \not= \omega_i\), the Radius Inequality implies that \(r(x') > 2\). Then as above, Proposition 6.7 implies that \(\xi \prec_K \eta\).

Let \(\xi = \xi_0 \prec_K \xi_1 \prec_K \cdots \prec_K \xi_k = \eta\) be the points of intersection of \(K\)-arc \([\xi, \eta]_K\) with \(R_0\), then \(\eta = \hat{\Phi}^k(\xi)\). As before, we have that \(n_\xi(t) \geq 0\) for \(0 \leq t \leq t_\eta\) where \(\eta = \Phi_{t_\eta}(\xi)\) and so also \(\rho_\xi(t) \geq 2\) for \(0 \leq t \leq t_\eta\).

Then there is an open neighborhood \(\xi \in U_\xi \subset R_0\) such that \(\hat{\Phi}^k|U_\xi\) is defined and is the composition of elements in \(G_K\). It follows that \(\hat{\Psi}|U_\xi = \hat{\Phi}^k|U_\xi\), and so \(\hat{\Psi}|U_\xi \in G_K\). The vertical line segments \(\{r = 2; z \neq \pm 1\} \cap \text{int}(D(\hat{\Psi})_{\prec})\) thus admit coverings by open sets \(U_\xi \subset R_0\) such that \(\hat{\Phi}|U_\xi\) is the restriction of an element of \(G_K\). Thus by the gluing condition Condition 9.3.5, there exists an open set \(U_{\psi_\prec} \subset R_0 \cap \text{int}(D(\hat{\Psi})_{\prec})\) containing \(\hat{\Phi}^k \cap \text{int}(D(\hat{\Psi})_{\prec})\) for which \(\hat{\Psi}_{\psi_\prec}\) is continuous, and the restriction of \(\psi_\prec = \hat{\Psi}_{\psi_\prec}\) defines a map in \(G_K\).

The proofs for the other two cases in (31) follow similarly, yielding domains denoted by \(U_{\psi_0}\) and \(U_{\psi_+}\) such that \(\hat{\Psi}_0|U_{\psi_0} \in G_K\) and \(\hat{\Psi}_+|U_{\psi_+} \in G_K\).

We thus obtain the following maps in \(G_K\)

\[
\psi_\prec = \hat{\Psi}_{\psi_\prec}, \quad \psi_0 = \hat{\Psi}_0|U_{\psi_0}, \quad \psi_+ = \hat{\Psi}_+|U_{\psi_+}.
\]

**Remark 9.7.** For convenience of notation in subsequent discussions, we will use the notation \(\psi\) for the union of the three maps \(\psi_\prec, \psi_0\) and \(\psi_+\) in (32). The domains of these three maps are disjoint, so \(\psi \in G_K\) by
the gluing condition Condition 9.3.5. Moreover, for $\xi$ in the domain of $\psi$ the meaning of $\psi(\xi)$ is then clear, as it is defined by exactly one of these maps.

We have established the existence of five special elements, $\{\phi_1^+, \phi_1^-, \phi_2^+, \phi_2^-, \psi\} \subset G_K$, each of which reflects aspects of the dynamics of the flow $\Phi_t$ which played key roles in analyzing the dynamics of the flow $\Phi_t$ in the previous sections of this work. Also, let $Id$ denote the identity map on $R_0$. We introduce the subset of $G_K$ generated by the compositions of these words:

**Definition 9.8.** Let $G_K^* \subset G_K$ denote the collection of all maps formed by compositions of the maps $\{Id, \phi_1^+, \phi_1^-, \phi_2^+, \phi_2^-, \psi\}$ and their restrictions to open subsets in their domains.

Note that $G_K^*$ need not satisfy the condition Definition 9.3.5 on unions of maps, so that $G_K^*$ is not a sub-pseudogroup of $G_K$. The reason for not imposing this condition, is that many dynamical properties for flows admit corresponding versions for local maps defined by compositions of maps in a generating set, but not if we allow for arbitrary unions as in condition (5). This issue is discussed further in Hurder [21] and Matsumoto [35]. Following the convention of [35], we say that $G_K^*$ is a pseudogroup, where the “*” refers to the definition as the composition of maps.

A set $S \subset R$ is syndetic if there exists $\nu_S > 0$ such that for all $a \in R$ the interval $[a, a + \nu_S]$ satisfies $S \cap [a, a + \nu_S] \neq \emptyset$. The set $S$ has bounded gaps if there exists $\mu_S > 0$ so that $|J| \leq \mu_S$ for all intervals $J \subset R$ with $J \cap S = \emptyset$. These two notions are clearly the same.

Let $x \in K$ have forward trapped orbit and let $x_t = \Phi_{t \ell}(x) \in T_K$, where $0 \leq t_0 < t_1 < \cdots$, be the sequence of transition points. Corollary 4.5 implies that there is an upper bound on the lengths $|t_{i+1} - t_i|$, so the set of transition times has bounded gaps and is a syndetic subset of $\{t \geq 0\}$. The study of the dynamical properties of the $K$-orbit in previous sections used this property repeatedly.

The dynamics of the pseudogroup $G_K$ acting on $R_0$ provides a second discrete model for the dynamics of the flow $\Phi_t$. The following result shows that the $G_K$-pseudogroup dynamics is an accurate model of the $K$-orbit dynamics along the infinite orbits in the region $\{r \geq 2\}$.

**Proposition 9.9.** Let $\xi \in R_0$ have infinite orbit for the flow $\Phi_t$ with $\rho_2(t) \geq 2$ for all $t$. Then the set $S_\xi = \{s \mid \Phi_s(\xi) \in R_0\}$ is syndetic, for a constant $\nu_K$ which is independent of $\xi$.

**Proof.** We first make some observations about transition points and the rectangle $R_0$. Recall that Lemma 4.1 lists the possible cases for a $W$-arc $[x, y]_K \subset K$ with lift $[x', y']_W$ in $\hat{W}$ and transition points $\{x, y\}$. Figures 9 and 10 help to visualize these possible cases. Note that there does not exist a $W$-arc $[x, y]_K$ for the case where $x \in S_2$ and $y \in E_1$. Also, for $x \in E_1$ and $y \in S_2$ or for $x \in E_2$ and $y \in S_1$, again no such $W$-arc exists by the facing property of the $\Psi_t$-flow.

The following results describe the cases where a $W$-arc $[x, y]_K \subset K$ intersects the rectangle $R_0$.

**Cases 9.10.** There are 7 cases where a $W$-arc $[x, y]_K$ always intersects $R_0$:

1. $x \in E_i$ for $i = 1, 2$ and $y \in E_1$
2. $x \in S_1$ and $y \in E_j$ for $j = 1, 2$
3. $x \in S_1$ and $y \in S_j$ for $j = 1, 2$
4. $x \in S_2$ and $y \in E_2$.

**Cases 9.11.** There are 6 cases where a $W$-arc $[x, y]_K$ may not intersect $R_0$:

1. $x \in E_i$ for $i = 1, 2$ and $y \in E_2$
2. $x \in E_i$ for $i = 1, 2$ and $y \in S_i$ (with $x \equiv y$)
3. $x \in S_2$ and $y \in S_i$ for $i = 1, 2$.

The cases where $x \in E_i$ for $i = 1, 2$ and $y \in E_2$ are notable, for they represent “entry/entry” transitions. Similarly, the cases where $x \in S_2$ and $y \in S_i$ for $i = 1, 2$, represent “exit/exit” transitions. These $W$-arcs will
intersect $R_0$ if $r(x)$ is sufficiently close to 2, but may not intersect $R_0$ for $r(x)$ near the upper limit $R_*$ defined in (18).

To prove Proposition 9.9, let $\xi_0 \in R_0$ such that $\xi_1 = \bar{\Phi}(\xi_0) = \Phi_{\epsilon_1}(\xi_0) \in R_0$ and $[\xi_0, \xi_1]_K$ is a $K$-orbit segment containing no interior intersections with $R_0$. We show that there is a uniform upper bound, independent of the point $\xi_0$, on the length of $[\xi_0, \xi_1]_K$.

First, suppose that $[\xi_0, \xi_1]_K$ contains no transition point, then it is a $W$-orbit segment and so $\xi_1 = \psi(\xi_0)$. If $[\xi_0, \xi_1]_K$ does not contain an interior point with $z = 0$, then the segment $[\xi_0, \xi_1]_K$ makes one complete revolution in $W$ from its start to finish in $R_0$ and so admits a uniform upper and lower bound on its length. Otherwise, if $[\xi_0, \xi_1]_K$ intersects the annulus $A = \{z = 0\}$, the point $\xi_0$ must lie below $A$ and flow counterclockwise until it meets $A$. This half of the flow traverses less than one revolution, and then flows clockwise to the point $\xi_1$ which must be symmetric with $\xi_0$ with respect to $A$. Thus, there is again a uniform upper bound on the length of the orbit segment between $\xi_0$ and $\xi_1$. Note that, as $\xi_0$ can be arbitrarily close to $A$, there is no lower bound on this length.

If $[\xi_0, \xi_1]_K$ contains transition points, label them $\{x_1, \ldots, x_k\}$ where $x_i = \Phi_{\epsilon_i}(\xi_0)$ for $0 < t_1 < \cdots < t_k < s_1$ with $k \geq 1$. Note that by assumption, $r(x_i) \geq 2$ for all $1 \leq i \leq k$. The lengths of the segments $[\xi_0, x_1]_K$ and $[x_k, \xi_1]_K$ in $K$ admit a uniform upper (and lower) bound as the subsets $R_0$, $E_i$ and $S_i$ for $i = 1, 2$, are compact.

If $[\xi_0, \xi_1]_K$ contains exactly one transition point $x_1$, the above discussion shows that its length is bounded, as it is a union of two $K$-orbit segments, both with an endpoint in $R_0$. Moreover, if $x_1$ is a secondary entry point in $E_1$ then $\xi_1 = \bar{\phi}_1(\xi_0)$ and if $x_1$ is a secondary exit point in $S_1$ then $\xi_1 = \phi_1^*(\xi_0)$.

For the remaining cases where $k \geq 2$, note that by Corollary 4.5, the lengths of the arcs $[x_i, x_{i+1}]_K$ for $1 \leq i < k$ admit uniform upper (and lower) bounds. Thus, it suffices to show there is an upper bound on the index $k$, independent of the initial point $\xi_0$. Also, note that the assumption $[x_i, x_{i+1}]_K$ does not intersect $R_0$ limits the possibilities for these $K$-arcs to the cases listed in Cases 9.11. We obtain an upper bound estimate on the number of such $K$-arcs which can occur.

**Lemma 9.12.** There exists $N_*$ such that if $[x_1, x_k]_K$ is a segment of the $K$-orbit in $K$ with transition points $\{x_1, \ldots, x_k\}$ for $k \geq 2$, each $x_i$ a secondary entry point with $r(x_i) \geq 2$ and $[x_1, x_k]_K \cap R_0 = \emptyset$, then $k \leq N_*$. 

**Proof.** By assumption, $x_i$ is a secondary entry point for each $1 \leq i < k$, so there exists $x'_i \in L_i^-$ and $y'_i \neq x'_i$ satisfying $\tau(x'_i) = \tau(y'_i) = x_i$. Moreover, $y'_{i+1} \in L_{i+1}^-$ for $1 \leq i < k$, for $y'_{i+1} \in L_{i+1}^-$ implies $W$-arc $[x'_i, y'_{i+1}]_W \cap R_0 \neq \emptyset$, contrary to assumption. Thus, each $W$-arc $[x'_i, y'_{i+1}]_W$ flows from the point $x'_i \in \partial K^- W$ to the point $y'_{i+1} \in L_{i+1}^-$ as so misses the surface $L_i^-$. 

In fact, the $W$-orbit of each $x'_i$ must rise sufficiently fast vertically so that it crosses the annulus $A$ before intersecting $R_0$, where it reverses direction and then flows until it terminates at $y'_{i+1} \in L_{i+1}^-$. We note that this is an exceptional condition, in that with some choices of embeddings $\sigma_1$ and $\sigma_2$ it may be impossible to satisfy.

Note that there exists $\epsilon'' > 0$ such that for all $x' \in \partial K^- W$ with $2 \leq r(x') \leq 2 + \epsilon''$, the $W$-orbit of $x'$ intersects $R_0$ before intersecting $L_i^-$. Thus, $r(x'_i) \geq 2 + \epsilon''$ for $1 \leq i < k$. In particular, $r(x'_i) \geq 2 + \epsilon''$.

As $n_{x_i}(t_{i+1}) = n_{x_i}(t_i) + 1$ for $1 \leq i < k$, we apply the Radius Inequality recursively to obtain that $r(x'_{i+1}) > r(x'_i) \geq 2 + \epsilon''$. By Lemma 6.7, the number $k$ of successive secondary entry transitions in the $K$-orbit segment $[x_1, x_k]_K$ is bounded above by the constant $N(2 + \epsilon'')$ introduced in its proof. Set $N_* = N(2 + \epsilon'')$ and the result follows.

**Lemma 9.13.** There exists $N^* > 0$ so that if $[x_1, x_k]_K$ is a $K$-orbit segment with transition points $\{x_1, \ldots, x_k\}$ for $k \geq 2$, each $x_i$ is a secondary exit point with $r(x_i) \geq 2$ and $[x_1, x_k]_K \cap R_0 = \emptyset$, then $k \leq N^*$. 

**Proof.** For $1 \leq i < k$, $x_i$ is a secondary exit point so there exists $x'_i \in L_i^+$ satisfying $\tau(x'_i) = x_i$. A $W$-arc from $L_i^+$ to $L_j^+$ for $j = 1, 2$ must intersect $R_0$ as noted previously, so we must have $x'_i \in L_j^+$ for $1 \leq i < k$ and thus $y'_{i+1} \in L_j^+$ for $1 \leq i < k$. As well. Note that $y'_k \in L_j^+$ for either $j = 1$ or $j = 2$ is allowed.
There exists $\epsilon'' > 0$ such that for all $x' \in \mathcal{L}_2^+$ with $2 < r(x') \leq 2 + \epsilon''$, the $\mathcal{W}$-orbit of $x'$ must intersect $R_0$ before it exits $\mathcal{W}$ through $\partial_\infty \mathcal{W}$. Thus, we must have $r(x_i) > 2 + \epsilon''$ for $1 \leq i < k$.

Let $0 < t_1 < \cdots < t_k$ be such that $x_i = \Phi_{t_i}(x)$ for $1 \leq i \leq k$. Then the level function satisfies $n_{x_i}(t_i) = 1 - i$ for $0 \leq i \leq k$ and thus $2 < r(x_i) < r(x'_i)$ for all $0 \leq i < k$. By the Radius Inequality, using the same argument as in the proof of Lemma 6.1, there exists $N'$ such that $i \geq N'$ implies that $r(x'_i) \leq 2 + \epsilon''$. By the choice of $\epsilon''$ this implies that $[x'_i, y_{i+1}]$ intersects $R_0$. Thus, we must have $k \leq N'$ and the result follows. □

We now conclude the proof of Proposition 9.9 for the cases $k \geq 2$, which involves an analysis of the possible cases which can arise for the $\mathcal{K}$-arcs $[x_i, x_{i+1}]$ for $1 \leq i < k$.

- If $x_i \in E_1$ then $x_{i+1} \in E_2$ is possible though “exceptional”, while $x_{i+1} \in S_j$ implies $j = 1$ and $x_i \equiv x_{i+1}$.
- If $x_i \in E_2$ then $x_{i+1} \in S_1$ is not possible, while if $x_{i+1} \in S_2$ then $x_i \equiv x_{i+1}$. The case $x_{i+1} \in E_2$ is possible, although exceptional and then Lemma 9.12 implies that we can repeat this case at most $N_*$ times to yield consecutive secondary entry points in $E_2$, before there is a transition point in $S_2$.

Combining these two cases, it follows that if $x_i \in E_j$ then after at most $N_* + 1$ transition points, there follows a secondary exit point.

- If $x_i \in S_1$ then the $\mathcal{K}$-arc $[x_i, x_{i+1}]$ must intersect $R_0$ for all $x_{i+1}$.
- If $x_i \in S_2$ and $x_{i+1} \in S_1$, then the $\mathcal{K}$-arc $[x_i, x_{i+1}]$ must be followed by a $\mathcal{K}$-arc which intersects $R_0$. If $x_i \in S_2$ and $x_{i+1} \in S_2$, then by Lemma 9.13 this case can be repeated successively at most $N_*$ times before the path must intersect $R_0$.

Combining all possible cases above, starting with $x_1$, the number of possible cases which can occur is bounded by $k \leq 3 + N_* + N_*$. Thus, there is a uniformly bounded number of transition points $\{x_1, \ldots, x_k\}$ which can arise in a $\mathcal{K}$-orbit segment $[x_1, x_k]$ which does not intersect $R_0$.

The following consequence of Proposition 9.9 shows that, in essence, the dynamical properties of $\Phi_t$ restricted to the non-wandering set $\Omega$ are determined by the action of the pseudogroup $G_K$ restricted to the compact invariant subset $\Omega \cap R_0$.

**Corollary 9.14.** Let $x \in \Omega$, then there exists $-\nu_K \leq t_x \leq \nu_K$ such that $\Phi_{t_x}(x) \in R_0$.

Recall that the pseudo-group $G_K^*$ is the subset of $G_K$ generated by compositions of maps in the collection $\{\phi^+_1, \phi^-_1, \phi^+_2, \phi^-_2, \psi\}$. It is natural to ask if the actions of $G_K$ and $G_K^*$ on $R_0$ are equivalent, which leads to the consideration of induced maps in $G_K$ which are not products of these generators. These maps are related to the maps appearing in the list Cases 9.11. In the next result, we show that the dynamics of $G_K^*$ and $G_K$ restricted to the non-wandering set $\Omega$ agree, at least for points $x \in R_0$ with $2 \leq r(x) \leq r_\epsilon$ where $r_\epsilon$ is the “exceptional radius” as defined in (33) below.

Consider the $\mathcal{K}$-arcs as in Cases 9.11. Given $x' \in L_1^-$ with $2 < r(x') \leq 2 + \epsilon''$ the $\mathcal{W}$-orbit of $x'$ intersects the rectangle $R_0$ before intersecting the surface $L_2^-$, as in the proof of Lemma 9.12. Then this case does not arise if $2 \leq r(x) \leq 2 + \epsilon''$ for $x = \tau(x')$.

Consider next the $\mathcal{K}$-arcs as in Cases 9.11.3. Recall from the proof of Lemma 9.13 that for $x' \in L_1^+$ with $2 < r(x') \leq 2 + \epsilon''$, the $\mathcal{W}$-orbit of $x'$ intersects $R_0$ before intersecting the exit region $\partial_\infty \mathcal{W}$. Then set 

$$r_\epsilon = \min\{2 + \epsilon'', 2 + \epsilon''\}.$$ 

**Proposition 9.15.** Let $\xi \in R_0$ and suppose $\eta = \hat{\Phi}(\xi)$, with $\eta = \Phi_{r_\epsilon}(\xi)$. Assume that $2 \leq \rho_\xi(t) \leq r_\epsilon$ for $0 \leq t \leq t_\eta$, then there exists $\phi \in G_K^*$ such that $\phi(\xi) = \eta$.

**Proof.** If the $\mathcal{K}$-segment $[\xi, \eta]_K$ contains no transition points, then $\hat{\Phi}(\xi) = \hat{\psi}(\xi) = \psi(\xi)$ and the claim follows. So consider the case when the $\mathcal{K}$-segment $[\xi, \eta]_K$ contains at least one transition point and let $x_1 = \Phi_{t_1}(\xi)$ with $0 < t_1 < t_\eta$ be the first transition point in the $\mathcal{K}$-segment $(\xi, \eta)_K$. Then $x_1$ is a secondary entry or exit point and we consider the possible cases.
Suppose that $x_1$ is a secondary entry point, so the $\mathcal{W}$-orbit of $\xi$ intersects one of the surfaces $\mathcal{L}_i^+$ in a point $y_i'$ with $\tau(y_i') = x_1$. Note that $r'(y_1') = r(\xi) \leq r_e$. Let $x_1' \in \mathcal{L}_i^-$ be such that $\tau(x_1') = x_1$, then $r(x_1') \leq 2 + \epsilon''$. Let $x_2'$ be the next transition point in the $K$-orbit of $\xi$, we have the three following cases:

- If $x_2' \in E_1$, then the $\mathcal{W}$-arc $[x_1, x_2]_K$ intersects $R_0$ at $\eta$ and thus $\eta = \phi_1^+(\xi)$.
- If $x_2' \in E_2$, then $\eta$ belongs also to the $\mathcal{W}$-arc $[x_1, x_2]_K$ since $r(x_1') \leq 2 + \epsilon''$. Then $\eta = \phi_1^+(\xi)$.
- If $x_2' \in S_i$ for $i = 1, 2$, then $x_1' \equiv x_2'$ and $x_2'$ is in the $\mathcal{W}$-orbit of $\tau^{-1}(\xi)$. In this case it might happen that $[x_1, x_2]_K$ does not intersects the rectangle $R_0$. If this is the case, we have to consider more transitions points. Let $x_i = \Phi_{t_i}(\xi)$ with $0 < t_1 < t_2 < t_3 < t_0$ and $1 \leq i \leq 3$, be the first three transition points.

According to Cases 9.10 if $x_3$ is a secondary entry point, the $\mathcal{W}$-arc $[x_2, x_3]_K$ must intersect $R_0$. Thus $\eta \in [x_2, x_3]_K$ and since $x_2$ is in the Wilson orbit of $\xi$, Proposition 6.7 implies that $\eta = \psi(\xi)$. If $x_3$ is a secondary exit point, the choice of $r_e$ implies that $[x_2, x_3]_K$ must intersect $R_0$ at $\eta$. Again we conclude that $\eta = \psi(\xi)$.

Next, suppose that $x_1$ is a secondary exit point, then the $\mathcal{W}$-orbit of $\xi$ exits through $\partial_K^+ \mathcal{W}$ in a point $y_i' \in L_i^+$ with $\tau(y_i') = x_1$, for $i = 1, 2$. Let $x_1' \in L_i^+$ be such that $\tau(x_1') = x_1$.

Assume first that $x_1 \in S_1$. Let $x_2$ be the following transition point in the $K$-orbit of $\xi$. Cases 9.10 imply that the $\mathcal{W}$-arc $[x_1, x_2]_K$ must intersect $R_0$, and thus $\eta = \phi_1^+(\xi)$.

We are left with the case $x_1 \in S_2$. If $x_2$ is a secondary entry point, then $x_2 \in E_2$ and the $\mathcal{W}$-arc $[x_1, x_2]_K$ must intersect $R_0$. We conclude that $\eta = \phi_2^+(\xi)$. If $x_2$ is a secondary exit point, then by the choice of $r_e$ we have that $r(x_1') < 2 + \epsilon''$ and thus the $\mathcal{W}$-arc $[x_1, x_2]_K$ must intersect $R_0$, implying that $\eta = \phi_2^+(\xi)$.

These cases exhaust the possibilities for the $K$-orbit segment $[\xi, \eta]_K$ so we have $\phi(\xi) = \eta$ where $\phi$ is one of the generators of $\mathcal{G}_K^*$.

**Proposition 9.16.** Let $\xi \in R_0$ have infinite orbit for the flow $\Phi_t$ with $r(\xi) < r_e$ and $\rho_\xi(t) \geq 2$ for all $t$. Then the set $S_*^\xi = \{ s \mid \Phi_s(\xi) \in \mathcal{G}_K^*(\xi) \subset R_0 , \ r(\Phi_s(\xi)) < r_e \}$ is syndetic, for a constant $\nu_e^*$ which is independent of $\xi$.

**Proof.** Let $s_0 \in S_*^\xi$ and let $s_1 \in S_*^\xi$ satisfy $s_0 < s_1$, such that $s_1$ is the least such value. We need to show that there exists a value $\nu_e^*$ independent of $s_0$ such that $s_1 - s_0 \leq \nu_e^*$.

It is given that $\xi \in R_0$ has infinite orbit with $\rho_\xi(t) \geq 2$ for all $t$, so the set $S_\xi = \{ s \mid \Phi_s(\xi) \in R_0 \}$ is syndetic in $\mathbb{R}$ with constant $\nu_e^*$ by Proposition 9.9. Also, by definition there is an inclusion $S_*^\xi \subset S_\xi$. Consider successive points $s_0, s_1 \in S_*^\xi$ with $s_0 < s_1$. It suffices to show that there exists $C(r_e) > 0$, depending on $r_e$ but independent of $\xi$, so that $[s_0, s_1] \cap \xi$ contains at most $C(r_e)$ points. We show this first for the case $s_0 \geq 0$.

Suppose that for all $s_0 \leq t \leq s_1$ we have $2 \leq \rho_\xi(t) \leq r_e$. Then by Proposition 9.15 the intersection $S_\xi \cap (s_0, s_1)$ is empty.

If $\rho_\xi(t) \leq r_e$ for all $t \geq 0$, then the above argument shows that $[0, \infty) \cap S_\xi = [0, \infty) \cap S_*^\xi$. Otherwise, let $t_1 > 0$ be the least time for which $\rho_\xi(t_1) \geq r_e$. Then $x_1 = \Phi_{t_1}(\xi)$ is a secondary entry point. By Proposition 6.7 there exists $T_{x_1} > 0$ such that $T_{x_1} = \Phi_{t_1+T_{x_1}}(\xi)$ is the secondary exit point facing $x_1$. Thus for $s = T_{x_1} + \epsilon$ and $\epsilon > 0$ small, $\rho_{T_{x_1} + \epsilon} < r_e$.

Consider the backwards flow of the secondary entry point $x_1$ to the first intersection of the orbit with $R_0$ to obtain a point $x_1 = \Phi_{u_1}(\xi) \in R_0$ where $0 \leq u_1 < t_1$. By the choice of $t_1$ and the remarks above, we have that $x_1 \in \mathcal{G}_K^*(\xi)$ and so $u_1 \in S_*^\xi$. Also, note that $t_1 - u_1 < \nu_e^*$ as $S_\xi$ is syndetic for the constant $\nu_e^*$.

Next, let $x_2 = \Phi_{u_2}(\xi)$ be the first intersection with $R_0$ of the forward orbit of $T_{x_1} = \Phi_{t_1+T_{x_1}}(\xi)$, so that $t_1 + T_{x_1} < u_2$ and $u_2 - (t_1 + T_{x_1}) < \nu_e^*$. Since $\rho_{T_{x_1} + \epsilon} < r_e$ for $\epsilon > 0$ sufficiently small, by the choice of $\nu_e^*$ in Proposition 9.3, there are no transition points in the $K$-orbit segment between $\Phi_{t_1+T_{x_1}}(\xi)$ and $x_2$. By Lemma 5.1 we have that $\xi_{\mathcal{W}} x_2$, which implies that $x_2 = \psi(\xi_1)$ for the generator $\psi \in \mathcal{G}_K^*$. Thus, $x_2 \in \mathcal{G}_K^*(\xi)$ with $r(x_2) < r_e$. Observe that $u_2 - u_1 < 2\nu_e^* + T_{x_1}$.
Lemma 6.1 and Corollary 6.8 imply that there exists $T_{r_0} > 0$ such that $T_{x_1} \leq T_{r_0}$ for all $x_1$ with $r(x_1) \geq r_0$.

Define $\nu^*_K = 2\nu_K + T_{r_0}$. We can then apply the above process recursively along the forward $K$-orbit of $\xi$ to obtain that $[0, \infty) \cap S^*_\xi$ is syndetic in $[0, \infty)$ for the constant $\nu^*_K$. The conclusion for the backward flow follows by reversing the time parameter as usual.

10. The level decomposition

We now begin the study of the dynamics of the Kuperberg flow $\Phi_t$ from a more topological point of view. Many of the results of the previous sections are given topological interpretations in this approach, which culminates in Section 19 with a description of the dynamics of the flow in terms of the structure of the “zippered lamination” $\mathcal{M}$ containing the minimal set $\Sigma$.

Recall that the periodic orbits $O_i$ of the Wilson flow are the boundary circles for the Reeb cylinder $R \subset \mathbb{W}$. We introduce the notched Reeb cylinder, $R' = R \cap \mathbb{W}'$, which has two closed “notches” removed from $R$ where it intersects the closed insertions $D_i \subset \mathbb{W}$ for $i = 1, 2$. Figure 18 illustrates the cylinder $R'$ inside $\mathbb{W}$.

Figure 18. The notched cylinder $R'$ embedded in $\mathbb{W}$

Consider the $K$-orbit of the image $\tau(R') \subset K$ and its closure

$\mathcal{M}_0 = \{ \Phi_t(\tau(R')) | -\infty < t < \infty \}$, \quad $\mathcal{M} = \overline{\mathcal{M}_0} \subset K$.

Note that since the special points $p_i^- = \tau(L_i^- \cap O_i)$ for $i = 1, 2$ are contained in $\mathcal{M}_0$, we have $\Sigma \subset \mathcal{M}$. Moreover, the flow $\Phi_t$ restricts to a flow on $\mathcal{M}$, so the dynamics of $\Phi_t$ on $\Sigma$ is defined by the restricted dynamics of the flow on $\mathcal{M}$.

The horizontal segments of the boundary of $R'$ which are not in the notches, are the orbit segments $O_i \cap \mathbb{W}$ of $\mathbb{W}$, while the vertical segments labeled $\gamma'$, $\lambda'$, $\lambda''$ and $\lambda'''$ in Figure 18 are transverse to the flow of $\mathbb{W}$. If $x \in \tau(\gamma')$ or $x \in \tau(\lambda')$ is on a vertical segment, the $K$-orbit of $x$ points into the notch. If in addition $z(x) \neq \pm 1$, then by Proposition 6.7, the forward $K$-orbit of $x$ returns in finite time to the opposite vertical boundary $\tau(\lambda')$, or $\tau(\lambda'' \lor \lambda''')$ respectively, of the notch. For each $0 < \epsilon < 1$, introduce the compact set $\mathcal{M}_0^\epsilon$ as follows. Observe that for $x \in \gamma'$ with $z(x) > -1$ Proposition 6.7 implies that there is a finite time $T_x$ such that $\Phi_{T_x}(\tau(x)) \in \tau(\gamma')$. Analogously, for $x \in \lambda'$ with $z(x) < 1$ there is a finite time $T_x$ such that $\Phi_{T_x}(\tau(x)) \in \tau(\lambda')$.

$\mathcal{M}_0^\epsilon = \tau(R') \cup \{ \Phi_t(x) | x \in \tau(\gamma'), z(x) \geq -1 + \epsilon, \; 0 \leq t \leq T_x \} \cup \{ \Phi_t(x) | x \in \tau(\lambda'), z(x) \leq 1 - \epsilon, \; 0 \leq t \leq T_x \}$. 

The regions added to $\tau(\mathcal{R}')$ “fill the gap” made by the notches in $\tau(\mathcal{R}')$, and yield the compact surface with boundary $\mathcal{M}_0$ embedded in $\mathcal{K}$ (the embedding $\tau$ of $\mathcal{R}'$ in $\mathcal{K}$ is illustrated in Figure 24). The time $T_x \to \infty$ as $x$ tends to the endpoint of $\gamma'$ or $\lambda'$, and the boundary curves of the compact surface $\mathcal{M}_0$ become increasing complicated, though the surface remains embedded at all times. The limit of these compact surfaces gives approximations to the set $\mathcal{M}_0$.

The properties of the level function $n_x(t)$ for the $\mathcal{K}$-orbit of $x \in \mathcal{K}$ were fundamental for the analysis of the orbital dynamics of the Kuperberg flow in previous sections. We next show that the level function along orbits tends to the endpoint of $\mathcal{M}_0$. The limit of these compact surfaces gives approximations to the set $\mathcal{M}_0$.

For each $x \in \mathcal{M}_0$ there exists some $y' \in \mathcal{R}'$ for which $y \in \tau(\mathcal{R}')$ such that $x = \Phi_{t_0}(y)$ for some $t \in \mathbb{R}$. The point $y$ is not unique, but as any such choice satisfies $r(y) = 2$, the proof of Proposition 7.1 implies that $r(x) \geq 2$. The following result is a consequence of this observation and previous results.

**Proposition 10.1.** There is a well-defined level function

$$n_0: \mathcal{M}_0 \to \mathbb{N} = \{0, 1, 2, \ldots\}.$$  

**Proof.** First, for $x \in \tau(\mathcal{R}')$ set $n_0(x) = 0$.

Let $x \in \mathcal{M}_0$, then there exists $y \in \tau(\mathcal{R}')$ such that $x = \Phi_{w_0}(y)$. Define $n_0(x) = n_y(s_0)$. Note that we allow both positive and negative values for $s_0$, using either formulas (12) or (13).

Let $w \in \tau(\mathcal{R}')$ be another point such that $x = \Phi_{w_1}(w)$. Assume without loss of generality that $y \prec w$ so that there exists $T > 0$ with $w = \Phi_T(y)$. Note that $n_y(s + T) = n_w(s) + n_y(T)$, so it suffices to show that $n_y(T) = 0$.

Suppose that $y \in \tau(\mathcal{R}')$ where $y = \tau(y')$ with $z(y') = \pm 1$, so that $y$ is on a special orbit. Then for $w \in \tau(\mathcal{R}')$ with $y \prec w$ we must have $w = \tau(w')$ where $z(w') = z(y')$. This implies there are no transition points in the $W$-orbit between $y'$ and $w'$, thus $n_y(T) = 0$.

Now suppose that $z(y') \neq \pm 1$, and let $0 \leq t_0 < t_1 < \cdots < t_k \leq T$ with $x_k = \Phi_{t_k}(y)$ be the transition points for the $\mathcal{K}$-orbit between $y$ and $w$, for $k \geq 0$. The case $k = 0$ is again immediate, so assume that $k \geq 1$. We show that $n_y(T) = 0$, which will follow using an inductive argument on the number of transition points $k$ between $y$ and $w$.

Note that $y' \in \mathcal{R}'$ and $z(y') \neq \pm 1$ implies that the first transition point $x_0 \in E_i$ for $i = 1, 2$, so $n_y(t_0) = 1$ and satisfies $r(x_0') > 2$. Let $\ell > 0$ be the least integer such that $n_y(t_\ell) = 0$, which exists by the proof of Proposition 6.7. Then $x_\ell$ is an exit point with $x_0 = x_\ell$ and so $x_\ell \in \tau(\mathcal{R}')$. Choose $u = \Phi_{t_\ell}(y)$ on the $\mathcal{K}$-orbit between $x_\ell$ and $x_{\ell+1}$, so that $n_y(t_\ell') = n_y(0) = 0$ and we have reduced the problem to showing that $n_y(T - t_\ell') = 0$, where the $\mathcal{K}$-orbit segment $[u, w]_{\mathcal{K}}$ now has $k - \ell - 1$ transition points. The claim now follows by induction.

Define the **level sets** of $\mathcal{M}_0$ as follows:

$$\mathcal{M}^n_0 = \{x \in \mathcal{M}_0 \mid n_0(x) \leq n\}, \ n = 0, 1, 2, \ldots.$$  

The set $\mathcal{M}^0_0$ contains the notched Reeb cylinder $\tau(\mathcal{R}')$ and the level 0 points in the boundary of the notches in $\tau(\mathcal{R}')$. The descriptions of the sets $\mathcal{M}^n_0$ for $n > 0$ is more subtle and will follow from a detailed study of the $\mathcal{K}$-orbit of the vertical segments $\gamma'$ and $\lambda'$ in Section 12.

### 11. Embedded surfaces and propellers

The invariant set $\mathcal{M}_0$ is the union of its level sets, as defined in (36). While the set $\mathcal{M}^n_0$ as described in the last section is rather simple, the description of the level sets $\mathcal{M}^n_0$ for $n > 0$ leads to the introduction of one of the main ideas of this work, the notion of finite and infinite propellers, which are obtained from the flow.
Consider a curve in the entry region, $\gamma \subset \partial_h^- \mathbb{W}$, with a parametrization $w(s) = (r(s), \theta(s), -2)$ for $0 \leq s \leq 1$, and assume that the map $w: [0, 1] \to \partial_h^- \mathbb{W}$ is a homeomorphism onto its image. We use the notation $w_s = w(s)$ when convenient, so that $w_0 = w(0)$ denotes the initial point and $w_1 = w(1)$ the terminal point of $\gamma$. For $\epsilon > 0$, assume that $r(w_0) = 3, r(w_1) = 2 + \epsilon$ and $2 + \epsilon < r(w_s) < 3$ for $0 < s < 1$.

The $\mathcal{W}$-orbits of the points in $\gamma$ traverse $\mathbb{W}$ from $\partial_h^- \mathbb{W}$ to $\partial_h^+ \mathbb{W}$ and hence the flow of $\gamma$ generates a compact invariant surface $P_\gamma \subset \mathbb{W}$. The surface $P_\gamma$ is parametrized by $(s, t) \mapsto \Psi_s(w(s))$ for $0 \leq s < 1$ and $0 < t < T_s$, where $T_s$ is the exit time for the $\mathcal{W}$-orbit of $w(s)$. Observe that as $s \to 1$ and $\epsilon \to 0$, Corollary 6.3 implies that the exit time $T_s \to \infty$.

The surface $P_\gamma$ is called a propeller, due to the nature of its shape in $\mathbb{R}^3$. It takes the form of a “tongue” wrapping around the core cylinder $\mathcal{C}(2+\epsilon)$ which contains the orbit of $w_1$.

To visualize the shape of this surface, consider the case where $\gamma$ is topologically transverse to the cylinders $\mathcal{C}(r_0) = \{r = r_0\}$ for $2 + \epsilon \leq r_0 \leq 3$. The transversality assumption implies that the radius $r(w_s)$ is monotone decreasing as $s$ increases. Figure 19 illustrates the surface $P_\gamma$ as a “flattened” propeller on the right and its embedding in $\mathbb{W}$ on the left. As $\epsilon \to 0$ the surface approaches the cylinder $\mathcal{C} = \{r = 2\}$ in an infinite spiraling manner.

![Figure 19. Embedded and flattened finite propeller](image)

We comment on the details in Figure 19. The horizontal boundary $\partial_h P_\gamma$ is composed of the initial curve $\gamma \subset \partial_h^- \mathbb{W}$ and its mirror image $\overline{\gamma} \subset \partial_h^+ \mathbb{W}$ via the entry/exit condition on the Wilson Plug. The vertical boundary $\partial_v P_\gamma$ is composed of the vertical segment $w_0 \times [-2, 2]$ in $\partial_v \mathbb{W}$ and the orbit $\{\Psi_t(w_1) \mid 0 \leq t \leq T_1\}$ which is the inner (or long) edge in the interior of $\mathbb{W}$. One way to visualize the surface, is to consider the product surface $\gamma \times [-2, 2]$ and then start deforming it by an isotopy which follows the flow lines of $\mathcal{W}$, as illustrated in Figure 19. In the right hand side of the figure, some of the orbits in the propeller are presented, while in the left hand side, just the boundary orbit is presented.

Consider the orbit $\{\Psi_t(w_1) \mid 0 \leq t \leq T_1\}$ of the endpoint $w_1$ with $r(w_1) = 2 + \epsilon$. The path $t \mapsto \Psi_t(w_1)$ makes a certain number of turns in the positive $S^1$-direction before reaching the core annulus $\mathcal{A}$ at $z = 0$. The Wilson vector field $\mathcal{W}$ is vertical on the plane $\mathcal{A}$, so the flow of $w_1$ then crosses $\mathcal{A}$, after which the orbit $\Psi_t(w_1)$ starts turning in the negative direction and ascending until it reaches $\partial_h^+ \mathbb{W}$. The point where the flow $\Psi_t(w_1)$ intersects $\mathcal{A}$ is called the tip of the propeller $P_\gamma$.

The anti-symmetry of the vector field $\mathcal{W}$ implies that the number of turns in one direction (considered as a real number) equals the number of turns in the opposite direction. To be precise, for $w_1 = (r_1, \theta_1, -2)$, let...
\( \Psi_t(w_1) = (r_1(t), \theta_1(t), z_1(t)) \) in coordinates. The function \( z_1(t) \) is monotone increasing and by the symmetry, we have \( z_1(T_1/2) = 0 \). Thus, the tip is the point \( \Psi_{T_1/2}(w_1) \).

Set \( \Theta(2 + \epsilon) = \theta(T_1/2) - \theta(0) \), where \( \theta(t) \) is a continuous function with \( \theta_1(t) = \theta_1(t) \mod (2\pi) \). The function \( \Theta(2 + \epsilon) \) measures the total angle advancement of the curve \( t \mapsto \Psi_t(w_1) \) between the initial point \( w_1 \) and the tip \( \Psi_{T_1/2}(w_1) \). The number \( \Theta(2 + \epsilon) \) depends only on the radius \( 2 + \epsilon \) of the point \( w_1 \), as the flow \( \Psi_t \) is rotationally symmetric by Proposition 2.1.

Note that \( \Theta(2 + \epsilon) \to \infty \) as \( \epsilon \to 0 \). Also, introduce the notation

\[
\Delta(2 + \epsilon) = \frac{\theta(0) - \theta(2 + \epsilon)}{2\pi} \mod (2\pi) .
\]

for the integer part of \( \Theta(2 + \epsilon)/2\pi \), which is the number of times that the curve \( \Psi_t(w_1) \) for \( 0 \leq t \leq T_1/2 \) makes a complete circuit around the cylinder \( C(2 + \epsilon) \).

Next, for fixed \( 0 \leq a < 2\pi \), consider the intersection of \( P_\gamma \) with a slice

\[
R_a = \{ (r, a, z) \mid 1 \leq r \leq 3, \quad -2 \leq z \leq 2 \}.
\]

The rectangle \( R_0 \) defined by (25) in Section 9 corresponds to the value \( a = \pi \). Each rectangle \( R_a \) is tangent to the Wilson flow along the annulus \( A \) and also near the boundary \( W \), but is transverse to the flow at all other points. The case when \( a = \Theta(2 + \epsilon) \mod (2\pi) \) is special, as the tip of the propeller is tangent to \( R_a \).

Assume that \( a \neq \Theta(2 + \epsilon) \mod (2\pi) \), then the flow \( \Psi_t(w_1) \) intersects \( R_a \) in a series of points on the line \( C(2 + \epsilon) \cap R_a \) that are paired, as illustrated in Figure 20. Moreover, the intersection \( P_\gamma \cap R_a \) consists of a finite sequence of arcs between the symmetrically paired points of \( \Psi_t(w_1) \cap R_a \). The number of such arcs is equal to \( \Delta(2 + \epsilon) \pm 1 \).

Let us now describe the intersection of \( P_\gamma \) with the annulus \( A = \{ z = 0 \} \), which traces out the midpoints of the curves \( t \mapsto \Psi_t(w(s)) \) for \( 0 \leq s \leq 1 \). That is, the intersection is the curve \( s \mapsto \Psi_{T_1/2}(w(s)) \in A \), which is a spiral, turning in the positive \( S^1 \) direction \( \Delta(2 + \epsilon) \) times around the core circle, as in Figure 22. The point of the curve on the boundary of \( A \) in Figure 22 corresponds to the orbit \( \Psi_t(w_0) \) and the point at the end of the spiral closest to the circle \( \{ r = 2 \} \) corresponds to the tip of \( P_\gamma \). If we change \( A \) for another annulus \( A_b = \{ z = b \} \) where \( b \neq 0 \), the intersection \( P_\gamma \cap A_b \) will be a spiral turning in the positive \( S^1 \)-direction that is strictly shorter than the one in \( A \). By symmetry, the traces of \( P_\gamma \) on \( A_{-b} \) and \( A_b \) are the same.

We comment on the details of Figure 20. The vertical line between the points \( (2, a, -1) \) and \( (2, a, 1) \) (marked in the figure simply by \( z = -1 \) and \( z = 1 \), respectively) is the trace of the Reeb cylinder in \( R_a \). The trace of a propeller in \( R_a \) is a collection of arcs that have their endpoints in the vertical line \( \{ r = 2 + \epsilon \} \). In the left hand figure, \( r(w_1) = 2 \) and the propeller in consideration is infinite. The curves form an infinite family, here just four arcs are shown, accumulating on the vertical line. The right hand figure illustrates the case \( r(w_1) > 2 \) and the propeller is finite.
Finally, consider the case where $\epsilon = 0$, so that the endpoint $w_1$ of $\gamma$ lies in the cylinder $C$. Then for $0 \leq s < 1$, we have $r(w(s)) > 2$, so the $W$-orbit of $w_\epsilon \in \partial^+_h W$ escapes from $W$. Define the curve $\overline{\gamma}$ in $\partial^+_h W$ to be the trace of these facing endpoints in $\partial^+_h W$, parametrized by $\overline{w}(s)$ for $0 \leq s < 1$, where $w(s) \equiv \overline{w}(s)$.

Define $w_1 = \lim_{s \to 1} w(s)$ so that $w_1 \equiv \overline{w}_1$.

Note that the forward $\Psi_t$-orbit of $w_1$ is asymptotic to the periodic orbit $O_1$, while the backward $\Psi_t$-orbit of $\overline{w}_1$ is asymptotic to the periodic orbit $O_2$. Introduce their “pseudo-orbit”,

$$
Z_\gamma = Z^-_\gamma \cup Z^+_\gamma, \quad Z^-_\gamma = \{ \Psi_t(w_1) \mid t \geq 0 \} \quad \text{and} \quad Z^+_\gamma = \{ \Psi_t(\overline{w}_1) \mid t \leq 0 \}
$$

Each curve $Z^\pm_\gamma$ traces out a semi-infinite ray in $C$ which spirals from the bottom or top face to a periodic orbit, and thus $Z_\gamma$ traces out two semi-infinite curves in $C$ spiraling to the periodic orbits $O_1 \cup O_2$.

For $0 < \epsilon \leq 1$, denote by $\gamma^\epsilon$ the curve with image $w([0, \epsilon])$, parametrized by

$$
w^\epsilon(s) = w(\epsilon \cdot s).
$$

**DEFINITION 11.1.** Let $\gamma$ be a curve parametrized by $w: [0, 1] \to W$ as above, with $r(w_0) = 3$ and $r(w_1) = 2$. Introduce the infinite propeller and its closure in $W$:

$$
P_\gamma = Z_\gamma \cup \bigcup_{\epsilon > 0} P_\gamma^\epsilon, \quad \overline{P}_\gamma = \bigcup_{\epsilon > 0} \overline{P}_\gamma^\epsilon.
$$
PROPOSITION 11.2. The closure $\mathcal{P}_\gamma$ of an infinite propeller contains the Reeb cylinder $\mathcal{R}$, with

$$\mathcal{P}_\gamma = P_\gamma \cup \mathcal{R}. \quad (42)$$

In particular, the periodic orbits $\mathcal{O}_1$ and $\mathcal{O}_2$ are contained in $\mathcal{P}_\gamma$.

Proof. The endpoints of the arcs in $P_\gamma \cap \mathcal{R}_a$ tend to points in $\mathcal{C} \cap \mathcal{R}_a$ as $\epsilon \to 0$, as illustrated in Figure 20, so the closure $\mathcal{P}_\gamma$ contains the set $\mathcal{Z}_\gamma$. Thus, the intersection $\{\Psi_t(w_s) | 0 \leq t \leq T_s\} \cap \mathcal{R}_a$ for $s \to 1$ contains pairs of points arbitrarily close to the intersections $\mathcal{O}_i \cap \mathcal{R}_a$ for $i = 1, 2$. The family of arcs connecting these points is nested with the vertical line $\mathcal{R} \cap \mathcal{R}_a$ as the inner boundary. Thus, $P_\gamma \cap \mathcal{R}_a$ contains arcs joining these points which are arbitrarily close to $\mathcal{R} \cap \mathcal{R}_a$ and so $\mathcal{R} \cap \mathcal{R}_a \subset \mathcal{P}_\gamma \cap \mathcal{R}_a$. \hfill \square

Note that the first-half $\mathcal{W}$-orbit segments $\{\Psi_t(w_s) | 0 \leq t \leq T_s/2\}$ for $s \to 1$ have $\mathcal{O}_1$ in their closure and the second-half $\mathcal{W}$-orbit segments $\{\Psi_t(w_s) | T_2/2 \leq t \leq T_s\}$ for $s \to 1$ have $\mathcal{O}_2$ in their closure.

12. Propellers and the level decomposition

In this section, we analyze the structure of the level decomposition of $\mathcal{M}_0 \subset \mathbb{K}$ introduced in Section 10 using the concepts of propellers introduced in the last section. A key point is the introduction of an “intuitive” labeling system for the collection of propellers generated by the flow of the notched Reeb cylinder. This labeling gives order to the propellers at each level, which grow in number at an exponential rate. A second key point is the introduction of an “intuitive” symmetry condition

$\partial_\mathcal{R}$

The endpoints of the arcs in $\mathcal{W}$ gives order to the propellers at each level, which grow in number at an exponential rate. A second key point is the introduction of an “intuitive” generic properties of the choices made in the construction of the Wilson flow $\mathcal{W}$ and on the insertions $\sigma_i$ for $i = 1, 2$. For this purpose, we formulate additional assumptions on the insertions $\sigma_i$ for $i = 1, 2$, which yield a stronger form of the Radius Inequality (KS) introduced by Kuperberg in [27].

Let $(r', \theta', z') = \sigma_i(x) \in D_i$ for $i = 1, 2$, where $x = (r, \theta, z) \in D_i$ is a point in the domain of $\sigma_i$. Let $\pi_z(r', \theta', z') = (r', \theta', -2)$ denote the projection of $\mathcal{W}$ along the $z'$-coordinate. We assume that $\sigma_i$ restricted to the bottom face, $\sigma_i: L_i^\perp \rightarrow \mathcal{W}$, has image transverse to the vertical fibers of $\pi_z$. Then $\pi_z \circ \sigma_i: L_i^\perp \rightarrow \mathcal{W}$ is a diffeomorphism into the face $\partial_\mathcal{W} \mathcal{W}$, with image denoted by $\mathcal{D}_i \subset \partial_\mathcal{W} \mathcal{W}$. Given this assumption, let $\vartheta_i = (\pi_z \circ \sigma_i)^{-1}: \mathcal{D}_i \rightarrow L_i^\perp$ denote the inverse map, so we have:

$$\vartheta_i(r', \theta', -2) = (r(\vartheta_i(r', \theta')), \theta(\vartheta_i(r', \theta')), -2) = (R_{i,r'}(\theta', -2), \Theta_{i,r'}(\theta', -2), -2). \quad (43)$$

We formalize the assumptions on the insertion maps $\sigma_i$ that are intuitively implicit in Figure 3. Set

HYPOTHESIS 12.1 (Strong Radius Inequality). For $i = 1, 2$, assume that:

1. $\sigma_i: L_i^\perp \rightarrow \mathcal{W}$ is transverse to the fibers of $\pi_z$;
2. $r' = r(\sigma_i(r, \theta, z)) < r$, except for $(2, \theta_i, z)$ and then $z(\sigma_i(2, \theta_i, z)) = (-1)^i$;
3. $\Theta_{i,r'}(\theta') = \theta(\vartheta_i(r', \theta', -2))$ is an increasing function of $\theta'$ for each fixed $r'$;
4. $R_{i,r'}(\theta') = r(\vartheta_i(r', \theta', -2))$ has non-vanishing derivative for $r' = 2$, except for the case of $\Theta_i$ defined by $\vartheta_i(2, \theta_i, -2) = (2, \theta_i, -2)$;
5. For $r'$ sufficiently close to 2, we require that the $\theta'$ derivative of $R_{i,r'}(\theta')$ vanish at a unique point denoted by $\theta'(i,r')$.

Consequently, each surface $L_i^\perp$ is transverse to the coordinate vector fields $\partial/\partial \theta$ and $\partial/\partial z$ on $\mathcal{W}$.

Recall from [8] that we have $\mathcal{W} = g(r, z) \frac{\partial}{\partial z} + f(r, z) \frac{\partial}{\partial r}$, where $g: \mathbb{R} \rightarrow [0, 1]$, which satisfies the “vertical” symmetry condition $g(r, z) = g(r, -z)$, $g(2, -1) = g(2, 1) = 0$. Also, we have that $g(r, z) = 1$ for $(r, z)$ near the boundary of $\mathcal{R}$, and that $g(r, z) > 0$ otherwise. These assumptions are made more precise by specifying that

$$g(r, z) = 1 \quad \text{for} \quad (r - 2)^2 + (|z| - 1)^2 \geq c_0^2 \quad (44)$$
where $0 < \epsilon_0 \leq 1/4$ is sufficiently small so that the closed $\epsilon_0$-neighborhood of each special point $p_i^\pm$ intersects the insertion regions $L_i^{\pm}$ in the interior of the face. We also require that $2 + \epsilon_0 \leq r_e$ where $r_e$ is the exceptional radius defined in [33]. Finally, we require that $g(r, z)$ is monotone increasing as a function of the distance $\sqrt{(r-2)^2 + (|z|-1)^2}$ from the special points $(2, -1)$ and $(2, 1)$.

As $g(r, z) \geq 0$, the first derivatives of $g$ must vanish at the points $(2, \pm 1)$ and the $2 \times 2$ Hessian matrix of second derivatives at these points must be positive indefinite. The function $g$ is said to be non-degenerate if its Hessian matrix is positive definite at the points $(2, \pm 1)$, and the value of $g(r, z)$ is a non-decreasing function of the distance from the points in the $\epsilon_0$-ball around each.

**HYPOTHESIS 12.2.** Assume that $f(r, z)$ satisfies the conditions (W1) to (W6) in Section 3 that the condition [44] holds and that $g$ is non-degenerate.

Hypotheses [12.1] and [12.2] are not required for the results in previous sections, though some version of these hypotheses appear to be implicitly assumed by certain conclusions stated in [17, 34].

We next apply these assumptions to the study of the $K$-orbit of the notched Reeb cylinder $R'$. First, note that for each $1 \leq r < 3$, if the intersection $\mathcal{C}(r) \cap L_i^-$ is non-empty, then it is a curve. Hypothesis [12.1] implies that each such arc of intersection in $\mathcal{C}(r)$ has the property that, as the $z$-coordinate increases along the curve, the $\theta$-coordinate decreases for the curve in $L_1^-$, or increases for the curve in $L_2^-$.

Consider the intersections of the faces $L_i^{\pm}$ with the Reeb cylinder $\mathcal{R}$,

\begin{align}
\gamma' &= \mathcal{R} \cap L_1^- , \quad \lambda' = \mathcal{R} \cap L_2^- ; \\
\gamma &= \sigma_1^{-1}(\gamma') , \quad \lambda = \sigma_1^{-1}(\lambda') ; \\
\lambda &= \sigma_1^{-1}(\lambda') , \quad \lambda' = \sigma_1^{-1}(\lambda').
\end{align}

which are arcs transverse to the $\Psi_t$-flow on $\mathcal{R}$, as illustrated in Figure 18. Label their preimages in $\partial_h^+ \mathcal{W}$ under the insertion maps $\sigma_i$ by

\begin{align}
\gamma &= \sigma_1^{-1}(\gamma') , \quad \lambda = \sigma_2^{-1}(\lambda') ; \\
\lambda &= \sigma_2^{-1}(\lambda') , \quad \lambda = \sigma_2^{-1}(\lambda').
\end{align}

One endpoint of the curve $\gamma$ is contained in the boundary $L_1^- \cap \{r = 3\}$ and the other endpoint is the special point $\sigma_1^{-1}(p_1^-) \in L_1^- \cap \{r = 2\}$. Similarly, one endpoint of the curve $\lambda$ is contained in the boundary $L_2^- \cap \{r = 3\}$ and the other endpoint is the special point $\sigma_2^{-1}(p_2^-) \in L_2^- \cap \{r = 2\}$.

Hypothesis [12.1] implies that both $\gamma$ and $\lambda$ are transverse to the cylinders $\{r = r_0\}$ for $2 < r_0 \leq 3$. As the $z$-coordinate of $x' \in \gamma'$ decreases towards $z = -1$, the radius coordinate $r$ of the corresponding point in $\gamma$ monotonically decreases to $r = 2$, while the angle coordinate $\theta$ monotonically increases towards $\theta_1$ as defined in (K7). For $\lambda'$, as the $z$-coordinate of $x' \in \lambda'$ increases towards $z = 1$, the radius of the corresponding point in $\lambda$ monotonically decreases, while the angle coordinate $\theta$ monotonically increases towards $\theta_2$ as defined in (K7). Thus, the graphs of the curves $\gamma$ and $\lambda$ in $\partial_h^- \mathcal{W}$ appear as in Figure 23.

**Figure 23.** The curves $\gamma$ and $\lambda$ in $\partial_h^- \mathcal{W}$

**Lemma 12.3.** The curve $\sigma_i \in L_i^+$ is the facing curve to $\gamma \subset L_1^-$ and $\lambda \subset L_2^-$ faces $\lambda \subset L_2^-$. Moreover, for each point $x \in \gamma$ with $r(x) > 2$, the facing point $\sigma_i$ satisfies $x \prec_K \sigma_i$. Similarly, for each point $y \in \lambda$ with $r(y) > 2$, the facing point $\sigma_i$ satisfies $y \prec_K \sigma_i$. 
Proof. The fact that $\overline{\tau}$ is facing to $\gamma$ and that $\overline{\lambda}$ is facing to $\lambda$, follows from the construction of the insertions $\sigma_i$. The assertions $x \prec_K \overline{\tau}$ for $r(x) > 2$ and $y \prec_K \overline{\gamma}$ for $r(y) > 2$, then follow from Proposition 6.7. □

Let $\gamma$ be parametrized by $w: [0, 1] \to \mathbb{W}$, with $r(w(0)) = 3$ and $r(w(1)) = 2$. For $0 \leq \epsilon \leq 1$, define $\gamma^\epsilon$ by $w(\epsilon \cdot s)$ for $0 \leq s \leq 1$, as in (40). Then Lemma 12.3 implies that for $0 < \epsilon < 1$ and $0 \leq s \leq 1$, we have $\gamma^\epsilon(s) \prec_K \gamma(s)$. However, the $W$-orbits of the points $w_1 = w(1)$ and $\overline{w}_1 \equiv w_1$ are both trapped, so cannot satisfy $w_1 \prec_W \overline{w}_1$. Thus, the curves $\gamma$ and $\overline{\gamma}$ are the horizontal boundary curves in $\partial^h_{\overline{w}} \mathbb{W}$ of the infinite propeller $P_\gamma$ defined by the $\Phi_t$-flow of $\gamma$. Similar conclusions hold for $\lambda$, $\overline{\lambda}$ and the propeller $P_\lambda$.

Note that in the Definition 11.1 of the infinite propeller $P_\gamma$, we formed the union of the propellers $P_{\gamma'}$ defined by the curves $\gamma'$ for $0 < \epsilon < 1$, with the two trapped orbits $Z_\gamma$. The $W$-orbit given by the “long edge” of each $P_{\gamma'}$ is a finite $W$-arc, but as $\epsilon \to 0$ their limit converges to the union $Z_\gamma$ of infinite orbits. This behavior is reminiscent of the “Moving Leaf Lemma” in [14, 48], which is the key to understanding the orbit behavior in the counter-examples to the Periodic Orbit Conjecture [13].

The $K$-orbits of the curves $\gamma$ and $\lambda$ projected to $K$ have a complicated, hierarchical structure, which we next describe using their $\Phi_t$-flows as the starting model. Define the notched propellers of $\gamma$ and $\lambda$ by $P'_\gamma = P_\gamma \cap \mathbb{W}'$ and $P'_\lambda = P_\lambda \cap \mathbb{W}'$, respectively. Note that the vertical “transverse” boundary curves for the notches are not included in $P'_\gamma$ and $P'_\lambda$.

For $x \in \tau(\mathcal{R}')$, the level function $n_\omega(t)$ increases from 0 to 1 when the orbit of $x$ intersects either curve $\tau(\gamma)$ or $\tau(\lambda)$, then drops back to 0 when it exits through the curves $\tau(\overline{\gamma})$ or $\tau(\overline{\lambda})$. Thus, we have

$$\omega^0 \subset \tau(\mathcal{R}' \cup \gamma \cup \lambda)$$

which is a cylinder, minus two rectangles, embedded in $\mathbb{R}^3$ as a folded eight having two parts that are tangent to the boundary of the notches, as in Figure 24.

![Figure 24. Embedding of $\mathcal{R}'$ in $K$](image)

We comment on the details of Figure 24. Note that the embedding $\tau$ of $\mathcal{R}'$ in $K$ differs from its inclusion in $\mathbb{W}$ as illustrated in Figure 18 as the Reeb cylinder in embedded as a folded figure-eight. The insertions $\sigma_i$ fold parts of the inner loop in the folded eight and make them tangent to the erased rectangles. This process brings two vertical lines in the cylinder to arcs contained in the erased boundary of the rectangles, covering the middle half of it. The remaining portions on each interval correspond to the cylindrical complement $C - \mathcal{R}$, and will be considered later in Section 13.

The set $\omega^0_1$ again has a simple intuitive description. It is obtained by attaching the points in $\omega^0_1$ of level 1 to $\omega^0_2$. The curves $\tau(\gamma)$ or $\tau(\lambda)$ were observed to have level 1, and thus the points in their $W$-orbits which lie in $\mathbb{W}'$ are also at level 1. In particular, the images $\tau(P'_\gamma)$ and $\tau(P'_\lambda)$ are at level 1, so are contained in $\omega^0_2$. 

Each of the infinite propellers $\tau(P'_\gamma)$ and $\tau(P'_\lambda)$ is obtained by removing an infinite sequence of notches from the propellers $P_\gamma$ and $P_\lambda$ and then applying $\tau$. There are two types of notches:

1. an infinite collection of notches, each having a corner containing a point of level 2 in the intersection of the $K$-orbit of a special point $p_i^\pm$ with the surfaces $E_j$ for $j = 1, 2$;
2. a finite number, possibly zero, of interior notches corresponding to the intersections of $P_\gamma$ and $P_\lambda$ with $D_j$ for $j = 1, 2$, which do not contain points in the $\Phi_t$-orbit of the special points.

**Remark 12.4.** The intersections of the second type give rise to what we call “bubbles” in the propeller and are discussed in detail later in this section and in Sections 15 and 18.

The precise shape of propellers depends on the choices made in the construction of the Kuperberg plug. In this section and Section 15 we consider a first type of internal notches and generated bubbles that can arise.

In Section 15 we introduce a new hypothesis on the construction that allow to give a more accurate description of the shape of propellers. This analysis is thus postponed until Section 18. One consequence of it will be another possible situation where internal notches and bubbles arise, as explained at the end of that section.

The construction of the set $\mathcal{M}^0_0$ uses “gluing” of propellers at higher level to the boundaries of these deletions from the infinite propellers at level 1. In order to give a more precise description of $\mathcal{M}^1_0$, in preparation for describing the nuances of the construction of $\mathcal{M}^0_0$ for $n \geq 2$, we develop an indexing system to label these intersections.

Recall from (11) that for $i = 1, 2$, $p_i^\pm = \tau(O_i \cap L_i^\pm)$ is called a special point. The corresponding points $\omega_i \in \mathbb{R}_0$ for $i = 1, 2$, as in (27), are used to define the level function along the special orbits. That is, the level function on $\mathcal{M}_0$ along the $K$-orbit of $\omega_i$ is defined by $n_0(x) = n_{\omega_i}(t_x)$ for $x = \Phi_{t_x}(\omega_i)$. Note that to obtain the full $K$-orbits of $\omega_i$, it is necessary to consider both their forward and backward orbits.

The first transition point for the forward $K$-orbit of $\omega_1$ is the entry point $p^-_1 \in E_1$ for which $n_0(p^-_1) = 1$. Set $p(1) = \tau^{-1}(p^-_1) \in L^-_1$ and note that $r(p(1)) = 2$. The forward $\mathcal{W}$-orbit of $p(1)$ is trapped in the region $\mathcal{C} \cap \{z < -1\}$ and thus intercepts $L^-_1 \cap \mathcal{C}$ in an infinite sequence of points with increasing $z$-coordinates between $-2$ and $-1$. Label these points $p'(1; 1, \ell)$ for $\ell \geq 0$.

Note that $r(p'(1; 1, \ell)) = 2$ for all $\ell \geq 0$ and we have

$$-2 < z(p'(1; 1, 0)) < \cdots < z(p'(1; 1, \ell)) < z(p'(1; 1, \ell + 1)) < \cdots < -1$$

where $z(p'(1; 1, \ell)) \to -1$ as $\ell \to \infty$.

Set $p(1; 1, \ell) = \sigma^{-1}_\ell(p'(1; 1, \ell)) \in L^-_1$ for $\ell \geq 0$. Then $r(p(1; 1, \ell)) > 2$ by the Radius Inequality (K8) and the sequence $p(1; 1, \ell)$ accumulates in $L^-_1$ on $p(1)$ as $\ell \to \infty$. Hence $r(p(1; 1, \ell)) \to 2$ as $\ell \to \infty$. Note that $n_0(\tau(p(1; 1, \ell))) = 2$ for all $\ell \geq 0$.

Similarly, the first transition point for the forward $K$-orbit of $\omega_2$ is the entry point $p^-_2 \in E_2$ with $n_0(p^-_2) = 1$. Set $p(2) = \tau^{-1}(p^-_2) \in L^-_2$ and note that $r(p(2)) = 2$.

The forward $\mathcal{W}$-orbit of $p(2)$ is also trapped in the region $\mathcal{C} \cap \{z < -1\}$ and thus intercepts $L^-_2 \cap \mathcal{C}$ in an infinite sequence of points with increasing $z$-coordinates also between $-2$ and $-1$. Label these points $p'(2; 1, \ell)$ for $\ell \geq 0$.

Note that $r(p'(2; 1, \ell)) = 2$ for all $\ell \geq 0$, and we have

$$-2 < z(p'(2; 1, 0)) < \cdots < z(p'(2; 1, \ell)) < z(p'(2; 1, \ell + 1)) < \cdots < -1$$

where $z(p'(2; 1, \ell)) \to -1$ as $\ell \to \infty$.

Set $p(2; 1, \ell) = \sigma^{-1}_\ell(p'(2; 1, \ell)) \in L^-_1$ for $\ell \geq 0$. Again, $r(p(2; 1, \ell)) > 2$ by the Radius Inequality (K8) and the sequence $p(2; 1, \ell)$ also accumulates in $L^-_1$ on $p(2)$ as $\ell \to \infty$. Thus, $r(p(2; 1, \ell)) \to 2$ as $\ell \to \infty$ and $n_0(\tau(p(2; 1, \ell))) = 2$ for all $\ell \geq 0$. 
LEMMA 12.5. The sequences \{p'(1; 1, ℓ) | ℓ ≥ 0\} and \{p'(2; 1, ℓ′) | ℓ′ ≥ 0\} are interlaced on the line segment \(C \cap L^+_i \cap \{z < -1\} \subset \mathbb{W}\). If \(z(p'(1; 1, 0)) < z(p'(2; 1, 0))\) then we have
\[
−2 < \cdots < z(p'(1; 1, ℓ)) < z(p'(2; 1, ℓ)) < z(p'(1; 1, ℓ + 1)) < \cdots < −1.
\]
The analogous conclusion holds when \(z(p'(2; 1, 0)) < z(p'(1; 1, 0))\).

Proof. Observe that \(L^+_i\) follows \(L^+_2\) in the direction of the \(θ\)-coordinate in \(\mathbb{W}\). Since \(p'(1; 1, 0)\) and \(p'(2; 1, 0)\) are the first intersections of the \(W\)-orbit of \(p(1)\) and \(p(2)\) with \(L^+_i\), we cannot predict which is below. Assuming that \(z(p'(1; 1, 0)) < z(p'(2; 1, 0))\), the inequality \(z(p'(2; 1, ℓ)) < z(p'(1; 1, ℓ + 1))\), for \(ℓ ≥ 1\), follows from the fact that the \(Ψ\)-flow preserves the cylinder \(C\) and so preserves the height relationship. The case when \(z(p'(2; 1, 0)) < z(p'(1; 1, 0))\) follows in the same way.

Next, consider the backward orbits of the points \(ω_i\), for \(i = 1, 2\), which intersect \(S_i\) in the points \(p^+_i\) with \(τ^{-1}(p^+_i) \in L^+_i\) and \(r(τ^{-1}(p^+_i)) = 2\). Thus, the backward Wilson orbits of \(τ^{-1}(p^+_i)\) for \(i = 1, 2\) are trapped in the region \(C \cap \{z > 1\}\) and so intersect \(L^+_2\) in infinite sequences of points with \(r = 2\) and \(z\)-coordinates between 1 and 2.

For the backward \(W\)-orbit of \(τ^{-1}(p^+_1)\), label these points \(p'(1; 2, ℓ) \in L^+_2\), for \(ℓ ≥ 0\), with \(r(p'(1; 2, ℓ)) = 2\) and \(1 < z(p'(1; 2, ℓ)) < 2\), where \(z(p'(1; 2, ℓ)) → 1\) as \(ℓ → ∞\). Set \(p(1; 2, ℓ) = σ_2^{-1}(p'(1; 2, ℓ)) \in L^+_2\). We then have \(n_0(τ(p(1; 2, ℓ))) = 2\) for \(ℓ ≥ 0\) by formula 13. The Radius Inequality (K8) implies that \(r(p(1; 2, ℓ)) > 2\) and note that the sequence \(p(1; 2, ℓ)\) accumulates on \(p(2)\) as \(ℓ → ∞\). Thus, \(r(p(1; 2, ℓ)) → 2\) as \(ℓ → ∞\).

Similarly, the backward \(W\)-orbit of \(τ^{-1}(p^+_2)\) intersects \(L^+_2\) in a sequence of points with \(r = 2\) and \(z\)-coordinate between 1 and 2. Label these points \(p'(2; 2, ℓ) \in L^+_2\), for \(ℓ ≥ 0\). Then \(r(p'(2; 2, ℓ)) = 2\) and \(1 < z(p'(2; 2, ℓ)) < 2\), where \(z(p'(2; 2, ℓ)) → 1\) as \(ℓ → ∞\). Set \(p(2; 2, ℓ) = σ_2^{-1}(p'(2; 2, ℓ)) \in L^+_2\). Again, we have \(n_0(τ(p(2; 2, ℓ))) = 2\) for \(ℓ ≥ 0\) by formula 13. Then \(r(p(2; 2, ℓ)) > 2\) by the Radius Inequality (K8) and the sequence \(p(2; 2, ℓ)\) accumulates on \(p(2)\) as \(ℓ → ∞\). Thus, \(r(p(2; 2, ℓ)) → 2\) as \(ℓ → ∞\).

The analog of Lemma 12.5 follows by the same arguments.

LEMMA 12.6. The sequences \{p'(1; 2, ℓ) | ℓ ≥ 0\} and \{p'(2; 2, ℓ′) | ℓ′ ≥ 0\} are interlaced on the line segment \(C \cap L^+_2 \cap \{z > 1\} \subset \mathbb{W}\). If \(z(p'(1; 2, 0)) < z(p'(2; 2, 0))\) then
\[
1 < \cdots < z(p'(2; 2, ℓ + 1)) < z(p'(1; 2, ℓ)) < z(p'(2; 2, ℓ)) < \cdots < 2.
\]
The analogous conclusion holds when \(z(p'(2; 2, 0)) < z(p'(1; 2, 0))\).

REMARK 12.7. The points \(τ(p(1; ·, ·))\) belong to the \(K\)-orbit of \(ω_1\), the points \(τ(p(2; ·, ·))\) belong to the \(K\)-orbit of \(ω_2\), while the points \(τ(p'(·, 1, ·)) \in E_1\) and the points \(τ(p'(·, 2, ·)) \in E_2\).

Next, we consider in detail the intersections of the propellers \(P_γ\) and \(P_λ\) with the surfaces \(L^+_i\) for \(i = 1, 2\). Recall that \(L^+_i\) was chosen in Section 3 to be transverse to the vector field \(Ψ\) and the insertion \(D_1\) is obtained from the \(Ψ\)-flow of its points. It follows that the surfaces \(L^+_i\) intersect the propellers \(P_γ\) and \(P_λ\) transversally, thus each such intersection must be a union of closed line segments whose boundaries are contained in the boundaries of either \(L^+_i\) or in the boundary of the propellers. The intersections of \(D_1\) with a propeller are then obtained as the \(Ψ\)-flow of each such line segment in \(L^+_i\), until it reaches the facing line segment in \(L^+_i\). We consider the possible cases for the line segments \(L^+_i \cap P_γ\). The analysis for the propeller \(P_λ\) will be analogous.

Recall that the intersection of \(P_γ\) with \(R_0\) is an infinite collection of arcs whose endpoints are on the vertical line \(\{r = 2\}\), the lower ones having \(z\)-coordinate less than \(-1\) and the upper ones having \(z\)-coordinate bigger than \(1\), as illustrated in Figure 20. The forward \(Ψ\)-flow of these arcs gives the intersection \(L^+_1 \cap P_γ\). For \(i = 1\), an arc in \(L^+_1 \cap P_γ\) either has both endpoints on the boundary \(∂L^+_1\), either has its upper endpoint on \(∂L^+_1\) and its lower endpoint is a point \(p'(1; 1, ℓ)\) for \(ℓ ≥ 0\). For \(i = 2\), an arc in \(L^+_2 \cap P_γ\) either has both endpoints on the boundary \(∂L^+_2\), either has its lower endpoint on \(∂L^+_2\) and its upper endpoint is a point \(p'(1; 2, ℓ)\) for \(ℓ ≥ 0\).
**DEFINITION 12.8.** If a segment of $\mathcal{L}_i^- \cap P_\gamma$ has both endpoints on $\partial \mathcal{L}_i^-$, the corresponding intersection of $P_\gamma$ with $D_i$ defines a “rectangular notch” in the interior of the propeller, called an interior notch for $P_\gamma$. If a segment of $\mathcal{L}_i^- \cap P_\gamma$ has an endpoint in the interior of $\mathcal{L}_i^-$, the corresponding intersection of $P_\gamma$ with $D_i$ defines a boundary notch for $P_\gamma$, or sometimes simply as a “ notch”.

The surface $P'_\gamma$ is obtained from $P_\gamma$ by deleting the interior and boundary notches for $i = 1$ and $i = 2$. This is illustrated in Figure 25.

![Figure 25. Internal and (boundary) notches of $P'_\gamma$](image)

For the propeller $P_\lambda$ formed by the $\Psi_t$-flow of the curve $\lambda$, analogous considerations and notations apply to the connected components of $P_\lambda \cap \mathcal{L}_i^-$ for $i = 1, 2$.

Observe that $P'_\gamma$ has a boundary notch for each intersection of the $W$-orbits of $p(1) = \tau^{-1}(p_1^-)$ and $\tau^{-1}(p_1^+)$ with $\mathcal{L}_1^- \cup \mathcal{L}_2^-$. Similarly, $P'_\lambda$ has a boundary notch for each intersection of the $W$-orbits of $p(2) = \tau^{-1}(p_2^-)$ and $\tau^{-1}(p_2^+)$ with $\mathcal{L}_1^- \cup \mathcal{L}_2^-$. There are an infinite number of such boundary notches.

In contrast, there are at most finitely many internal notches, since these correspond to the intersections of $P'_\gamma$ with $\mathcal{L}_1^- \cup \mathcal{L}_2^-$ for which the $W$-orbits of $p(1) = \tau^{-1}(p_1^-)$ and $\tau^{-1}(p_1^+)$ are away from the insertion region, or to the intersections of $P'_\lambda$ with $\mathcal{L}_1^- \cup \mathcal{L}_2^-$ for which the $W$-orbits of $p(2) = \tau^{-1}(p_2^-)$ and $\tau^{-1}(p_2^+)$ are away from the insertion region. Let $-b \geq 0$ denote the number of internal notches, with $b = 0$ if there are no internal notches, so that the $W$-orbit of $p(1)$ makes at least $|b|$ revolutions in the $\theta$-coordinate, before it intersects the surface $\mathcal{L}_1^-$.

We now describe the set $\mathcal{M}_0^\lambda$. The images $\tau(P'_\gamma)$ and $\tau(P'_\lambda)$ consist of points of level 1, and the exit boundaries of the notches in these propellers are also at level 1, so all belong to $\mathcal{M}_0^\lambda$.

We index the notches at level 2 as follows. The segment $\gamma$ is said to be based at its inner endpoint $p(1) = \tau^{-1}(p_1^-) \in \mathcal{L}_1^-$ and $\lambda$ to be based at its inner endpoint $p(2) = \tau^{-1}(p_2^-) \in \mathcal{L}_2^-$. Let $-b \geq 0$ denote the number of internal notches, with $b = 0$ if there are no internal notches, so that the $W$-orbit of $p(1)$ makes at least $|b|$ revolutions in the $\theta$-coordinate, before it intersects the surface $\mathcal{L}_1^-$.

Next, introduce labels for the four families of boundary notches which arise. It may help to consider the illustration Figure 25 to keep track of the following definitions.

Let $\gamma'(1, \ell) \subset \mathcal{L}_1^-$ for $b \leq \ell < \infty$ denote the curves corresponding to the intersection of $P_\gamma$ with $\mathcal{L}_1^-$, where $\gamma'(1, \ell)$ for $b \leq \ell < 0$ denotes an interior curve of the intersection with $\mathcal{L}_1^-$, assuming that such exists. Let $\gamma'(1, \ell)$ for $\ell \geq 0$ denote the boundary curve with lower endpoint $p'(1; 1, \ell)$. Set $\gamma(1, \ell) = \sigma^{-1}_1(\gamma'(1, \ell)) \subset \mathcal{L}_1^-$. We say that the curve $\gamma(1, \ell)$ for $\ell \geq 0$ is based at the point $p(1; 1, \ell)$. For all $x \in \tau(\gamma(1, \ell))$, we have $n_0(x) = 2$ and $r(x) > 2$.

Let $\lambda'(1, \ell) \subset \mathcal{L}_1^-$ for $b \leq \ell < \infty$ denote the curves corresponding to the intersection of $P_\lambda$ with $\mathcal{L}_1^-$, where $\lambda'(1, \ell)$ for $b \leq \ell < 0$ denotes an interior curve of the intersection with $\mathcal{L}_1^-$, assuming that such exists. Let $\lambda'(1, \ell)$ for $\ell \geq 0$ denote the boundary curve with lower endpoint $p'(2; 1, \ell)$. Set $\lambda(1, \ell) = \sigma^{-1}_1(\lambda'(1, \ell)) \subset \mathcal{L}_1^-$. We say that the curve $\lambda(1, \ell)$ for $\ell \geq 0$ is based at the point $p(2; 1, \ell)$. For all $x \in \tau(\lambda(1, \ell))$, we have $n_0(x) = 2$ and $r(x) > 2$. 
Let $\gamma'(2, \ell) \subset \mathcal{L}^{-2}$ for $b \leq \ell < \infty$ denote the curves corresponding to the intersection of $P_{\gamma}$ with $\mathcal{L}^{-2}$, where $\gamma'(2, \ell)$ for $b \leq \ell < 0$ denotes an interior curve of the intersection with $\mathcal{L}^{-2}$, assuming that such exists. Let $\gamma'(2, \ell)$ for $\ell \geq 0$ denote the boundary curve with upper endpoint $p'(1; 2, \ell)$. Set $\gamma(2, \ell) = \sigma_{-1}^{-1}(\gamma'(2, \ell)) \subset \mathcal{L}^{-2}$. We say that the curve $\gamma(2, \ell)$ for $\ell \geq 0$ is based at the point $p(1; 2, \ell)$. For all $x \in \tau(\gamma(2, \ell))$, we have $n_{0}(x) = 2$ and $r(x) > 2$.

Let $\lambda'(2, \ell) \subset \mathcal{L}^{-2}$ for $b \leq \ell < \infty$ denote the curves corresponding to the intersection of $P_{\lambda}$ with $\mathcal{L}^{-2}$, where $\lambda'(2, \ell)$ for $b \leq \ell < 0$ denotes an interior curve of the intersection with $\mathcal{L}^{-2}$, assuming that such exists. Let $\lambda'(2, \ell)$ for $\ell \geq 0$ denote the boundary curve with upper endpoint $p'(2; 2, \ell')$. Set $\lambda(2, \ell) = \sigma_{-1}^{-1}(\lambda'(2, \ell)) \subset \mathcal{L}^{-2}$. We say that the curve $\lambda(2, \ell)$ for $\ell \geq 0$ is based at the point $p(2; 2, \ell')$. For all $x \in \tau(\lambda(2, \ell))$, we have $n_{0}(x) = 2$ and $r(x) > 2$.

Lemmas 12.5 and 12.6 show that the families of points $\{p'(1; i, \ell) \mid \ell \geq 0\}$ and $\{p'(2; i, \ell') \mid \ell' \geq 0\}$ for $i = 1, 2$ are interlaced, so the same holds for the $\gamma$ and $\lambda$ curves in $\partial_{\text{up}}W$ and also for the curves with $\ell < 0$. That is, each $\lambda$-curve is between two $\gamma$-curves, and vice-versa, as illustrated in Figures 26 and 27.

We comment on the details of Figures 26 and 27. The curves in the figures come by pairs, in each pair one curve has level 1 and the other has level 2. We give details for the level 1 curves, that in the left side figures can be distinguished by the fact that one of their endpoints is in the vertical line $\{r = 2\}$. In the left side of Figure 26, the closest curve to $\gamma'$ is $\gamma'(1, 0)$, the boundary of the first boundary notch of $P_{\gamma}'$. The following level 1 curve is $\lambda'(1, 0)$ and the next one is $\gamma'(1, -1)$. Observe that $b$ might be $-1$ for $P_{\gamma}'$ and zero for $P_{\lambda}'$, but the number of internal notches is each propeller differs at most by 1. On the right side of Figure 26, the image under $\sigma_{-1}^{-1}$ of the curves is illustrated. Observe that the curves $\gamma(1, 0)$ and $\lambda(1, 0)$ have an endpoint in the dotted line, that is the image under $\sigma_{-1}^{-1}$ of the line $C \cap \{z \leq -1\} \cap L^{-1}_{1}$. Analogous considerations apply to Figure 27. We give the description of the level 2 curves in this section.

Finally, to complete the description of the level 1 set, note that for $i = 1, 2$, each curve $\tau(\gamma(i, \ell)) \subset E_{i}$ defines a facing curve $\tau(\gamma(i, \ell)) \subset S_{i}$. These facing curves in $S_{i}$ are at level 1 again, so belong to $\mathfrak{M}^{-1}_{0}$. Thus

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure26.png}
\caption{Curves of levels 1 and 2, in $\mathcal{L}^{-1}$ and in $L^{-1}_{1}$}
\end{figure}
we have

\[ \mathcal{M}_0^1 = \mathcal{M}_0^0 \cup \tau(P'_\gamma) \cup \tau(P'_\lambda) \cup \left\{ \bigcup_{\ell \geq b} \bigcup_{i=1}^2 \left[ \tau(\gamma(i,\ell)) \cup \tau(\lambda(i,\ell)) \right] \right\} \]

where the propellers and boundary curves are identified via the insertion maps \( \sigma_i \) as appropriate. Observe that in the above, we are assuming that \( b \leq 0 \) has a constant value for each family of curves. By the interlaced property, the number of internal notches in \( P'_\gamma \) and \( P'_\lambda \) differs at most by one.

For \( n \geq 1 \), the construction of \( \mathcal{M}_n^0 \) from \( \mathcal{M}_{n-1}^0 \) follows a procedure similar to the above pattern. The basic scheme is that for each image under \( \tau \) of a propeller at level \( n \), the entry curve along each of its notches is a curve at level \( n+1 \). The \( \Psi_t \)-flow of this curve yields a family of propellers at level \( n+1 \). The resulting propellers at level \( n+1 \) are contained in the region \( r > 2 \), so they are finite. We consider the case of \( \mathcal{M}_2^0 \) in some detail, to illustrate the general construction of \( \mathcal{M}_n^0 \) for \( n \geq 2 \).

Consider the curve \( \gamma(1,\ell) = \sigma_1^{-1}(\gamma'(1,\ell)) \subset L_1^- \). All the points on the curve \( \gamma(1,\ell) \) have radius greater than 2. Thus by Proposition 6.7, the \( \mathcal{K} \)-orbit of any point \( x \in \tau(\gamma(1,\ell)) \) contains the point \( \overline{x} \in S_1 \) such that \( x \equiv \overline{x} \). Let \( t_x > 0 \) be such that \( \Phi_{t_x}(x) = \overline{x} \), then

\[ S_{\gamma(1,\ell)} = \{ \Phi_t(x) \mid x \in \tau(\gamma(1,\ell)), 0 \leq t \leq t_x \}, \]

is a compact surface embedded in \( \mathcal{K} \). Similarly, we obtain compact surfaces \( S_{\lambda(1,\ell)} \), \( S_{\gamma(2,\ell)} \) and \( S_{\lambda(2,\ell)} \) embedded in \( \mathcal{K} \), for \( b \leq \ell < 0 \).

The surface \( S_{\gamma(1,\ell)} \) has points of level 2 and might have points at higher levels, but the level is uniformly bounded above by Proposition 15.4. It contributes to \( \mathcal{M}_2^0 \) with a compact set, a bubble, that we describe in detail in Section 15. To simplify the exposition, we assume for the rest of this section that \( b = 0 \) and thus that the propellers (at any level) do not have internal notches. We discuss the modifications needed to accommodate these internal notches later.

Consider the curve \( \gamma(1,\ell) = \sigma_1^{-1}(\gamma'(1,\ell)) \subset L_1^- \) where \( \ell \geq 0 \). It goes from the outer boundary of \( L_1^- \subset \partial_K \mathcal{W} \) to the point \( p(1;1,\ell) \) with \( r(p(1;1,\ell)) > 2 \), and all points on the curve \( \gamma(1,\ell) \) have radius greater than 2.
Thus, the $\Psi_t$-flow of the entire curve $\gamma(1, \ell)$ traverses $W$ in finite time, defining a finite propeller $P_{\gamma(1, \ell)}$ as in Section 11. By (47), the propeller $P_{\gamma(1, \ell)}$ intersects $L_1^-$ at most $\max_{x \in \gamma(1, \ell)} \Delta(r(x))$ times, for each curve in the collection $\{\gamma(1, \ell)\}_{\ell=0}^{\infty}$. In the same manner, we also obtain finite propellers $P_{\lambda(1, \ell)}$, $P_{\gamma(2, \ell)}$ and $P_{\lambda(2, \ell)}$ for $\ell \geq 0$.

Consider the corresponding four collections of “notched” finite propellers

\[
\left\{P_{\gamma(1, \ell)}'\right\}_{\ell=0}^{\infty}, \left\{P_{\lambda(1, \ell)}'\right\}_{\ell=0}^{\infty}, \left\{P_{\gamma(2, \ell)}'\right\}_{\ell=0}^{\infty}, \left\{P_{\lambda(2, \ell)}'\right\}_{\ell=0}^{\infty}
\]

defined by taking the intersection of the corresponding propellers with $W'$. Glue these notched propellers to $M_0^2$ using $\sigma_1$ and $\sigma_2$, where the points added with this gluing are level 2 points, hence are contained in $M_0^2$.

Each propeller in each of the four infinite collections in (54) yields a family of curves in $L_1^-$ and another family of curves in $L_2^-$. Since all the propellers we are considering are finite, the number of curves in the intersection of each propeller with $L_1^-$ and $L_2^-$ is finite. Note that the number of notches in a given propeller at level $n \geq 2$ may be zero. Moreover, for $i, j = 1, 2$ and $\ell \geq 0$, each base point $p(i, j, \ell)$ of the corresponding generating curve has radius greater than 2, so the $W$-orbit of the labeling points traces out the full boundary of the propeller it defines. This is in contrast to the case with the level 1 propellers, where both forward and backward orbits were required to reach all of the notches. We continue to use the same labeling scheme in levels larger than 1 for the base points of notches corresponding to the intersections with the faces of $L_1^-$ and $L_2^-$. Following the previous scheme, each entry region of a notch of $P_{\gamma(1, \ell)}'$ and $P_{\lambda(1, \ell)}'$ defines a curve denoted by $\gamma(i_1, \ell_1; i_2, \ell_2)$ and $\lambda(i_1, \ell_1; i_2, \ell_2)$ for $i_1, i_2 = 1, 2$, where $\ell_1, \ell_2 \geq 0$ and $\ell_2$ is bounded above by $\max_{x \in \gamma(i_1, \ell_1)} \Delta(r(x)) + 1 < \infty$ or $\max_{x \in \lambda(i_1, \ell_1)} \Delta(r(x)) + 1 < \infty$, accordingly. The index $i_2$ indicates that the curve is in $L_{\ell_2}^-$, while the indices $(i_1, \ell_1)$ indicate in which notched propeller of level 2 they are contained. Hence, for example, the curve $\gamma(i_1, \ell_1; 2, \ell_2)$ is in $L_2^-$ and belongs to $P_{\gamma(i_1, \ell_1)}'$. Some level 2 curves are represented in Figures 26 and 27. The details of these pictures are considered further in Section 13.

Corresponding to each curve defined by the intersection with an entry face, is the facing curve defined by the intersection with an exit face, denoted by $\gamma(i_1, \ell_1; i_2, \ell_2)$ and $\lambda(i_1, \ell_1; i_2, \ell_2)$. Then $M_0^2$ is obtained by attaching these exit curves to $M_0^1$, along with the level 2 finite propellers in (54).

The previous steps are now repeated recursively. Given $M_0^2$ for $n \geq 2$, we introduce families of curves defined by the entry curves in the notches of the propellers at level $n$,

\[
\gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n), \quad \lambda(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n)
\]

and their corresponding facing curves defined by the exit curves, for $i_1, i_2, \ldots, i_n = 1, 2$ and $\ell_i \geq 0$ which are bounded, except for $\ell_1$. The base points of these curves are

\[
p(1; i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \quad \text{and} \quad p(2; i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n),
\]

respectively. As before, $i_n$ indicates that the curve (or point) is in $L_{\ell_n}^-$ and the previous indices $(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1})$ indicate the propeller that contains the curve.

The curves in (55) generate finite propellers and the notched finite propellers associated to them. These are hence at level $n + 1$. Then $M_0^{n+1}$ is obtained from $M_0^n$ by attaching the infinite families of finite propellers at level $n + 1$ to each of the previously attached propellers in $M_0^n$, along with the exit curves at level $n + 1$ in these attached propellers. Thus, we obtain the nested compact sets

\[
M_0^0 \subset M_0^1 \subset \cdots \subset M_0^n \subset M_{0}^{n+1} \subset \cdots \subset M_0 \subset M = M
\]

Observe that in the construction of $M_0^n$ we added $4^n$ countable families of finite propellers, the images under $\tau$ of those in (54). In general, in stage $n$ of the construction, we add $2^n$ countable families of finite propellers, where each propeller is indexed by its base point $p(i_0; i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1})$ and each family has the indices $i_0, i_1, i_2, \ldots, i_{n-1}$ in common. However, for $(i_0; i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1})$ fixed, the number of $\ell_{n-1}$ for which there exists propellers with base curve $\gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1})$ if $i_0 = 1$ or
\[ \lambda(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1}) \text{ if } i_0 = 2, \text{ is bounded above by } \Delta(r) \text{ where } r \text{ is the maximum radius of the points in the curve } \gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-2}, \ell_{n-2}) \text{ or } \lambda(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-2}, \ell_{n-2}), \text{ accordingly.} \]

As observed above, the set \( \tau(R') \) is a cylinder, minus two rectangles, embedded as a “folded figure eight” as in Figure 24. One then adds two infinite propellers that wrap around \( \tau(R') \) to obtain \( M_1 \). The following steps in the construction add finite propellers to the infinite ones in \( M_1 \). The boundary of these finite propellers contain all of the finite *chou-fleurs* of Siebenmann, introduced in [17]. The term “chou-fleur” comes from the diagram of flattened propellers. In fact, if we draw \( R' \) as a rectangle, then we can add the flattened propellers as in Figure 28. The boundary represents \( K \)-orbits of the special points \( p_1^- \) and \( p_2^- \), and any finite part lying between two facing transition points is a chou-fleur.

![Figure 28. Flattened part of \( M_0 \)](image)

We comment on the details of Figure 28. The higher horizontal band in Figure 28 represents the notched Reeb cylinder \( R' \) to which the two infinite propellers in \( M_1 \) are attached. Part of the infinite propeller \( \tau(P'_\lambda) \) is the main vertical branch and only the base of the infinite propeller \( \tau(P'_\gamma) \) is pictured in this diagram. The propeller \( \tau(P'_\gamma) \) generates by its intersections with the insertions, the finite propellers in \( M_2 \), and so on. In \( K \), the width of the infinite propellers is the same as the width of \( R' \). The finite propellers are roughly the same width as the infinite ones, at least for a certain period of time. Hypothesis 12.1 implies that the finite propellers attached to \( \tau(P'_\gamma) \) become longer as we move downwards and also that the branching structure gets more and more complicated.

13. **Double propellers and pseudogroup dynamics**

In this section, we begin our analysis of the dynamics of the Kuperberg flow on \( M_0 \) and the dynamics of the pseudogroup \( G_K \) acting on \( R_0 \). A key technique introduced in this section is the the concept of *double propellers*, which are obtained from the \( K \)-orbit of special “parabolic” curves in \( \partial_R W \). The double propellers
define families of nested topological circles in \( R_0 \) which play a fundamental role in the study of the dynamics of the pseudogroup \( \mathcal{G}_K^* \) acting on \( R_0 \).

We first introduce the general notion of double propellers in \( \mathcal{W} \), then discuss their properties. We then define a labeling system for the double propellers generated by the flow \( \Phi_t \), which is based on the labeling system for propellers introduced in the last section. Finally, we consider the intersections of the double propellers with the rectangle \( R_0 \), which generates families of nested “ellipses”, and introduce a modified labeling system for these curves which corresponds to the action of the generators of the pseudogroup \( \mathcal{G}_K^* \) on \( R_0 \).

In the following, we assume that the constant \( b = 0 \), for \( b \) as introduced in Section 12, to index the internal notches in the propeller and postpone the discussion of the case \( b < 0 \) to Section 15.

Consider a smooth curve \( \Gamma \subset L \) parametrized by \( u: [0, 2] \to \partial h^{-1} \mathcal{W}, \) where \( u_s \equiv u(s) \), such that:

1. \( r(u_s) \geq 2 \) for all \( 0 \leq s \leq 2 \);
2. \( r(u_0) = r(u_2) = 3 \), so that both endpoints lie in the boundary \( \partial h^{-1} \mathcal{W} \cap \partial \mathcal{W} \);
3. \( \Gamma \) is topologically transverse to the cylinders \( C(r) \) for \( 2 \leq r \leq 3 \), except at the midpoint \( u_1 \).

It then follows that \( r(u_s) \geq r(u_1) = 2 + \epsilon \) for all \( 0 \leq s \leq 2 \), and some \( \epsilon \geq 0 \). See Figure 29 for an illustration in the case when \( \epsilon = 0 \).

Assume that \( \epsilon > 0 \), so that \( r(u_s) \geq 2 \) for all \( 0 \leq s \leq 2 \), then the \( \mathcal{W} \)-orbit of each \( u_s \) traverses \( \mathcal{W} \). Define \( T_s \) as the exit time for the \( \mathcal{W} \)-orbit of \( u_s \). The \( \mathcal{W} \)-orbits of the points in \( \Gamma \) form a surface embedded in \( \mathcal{W} \), whose boundary is contained in the boundary of \( \mathcal{W} \), and thus the surface separates \( \mathcal{W} \) into two connected components. This surface is denoted \( P_\Gamma \) and called the double propeller defined by the \( \Psi_t \)-flow of \( \Gamma \).

Consider the curves \( \gamma, \kappa \subset \partial h^{-1} \mathcal{W} \) obtained by dividing the curve \( \Gamma \) into two segments at the midpoint \( s = 1 \). Parametrize these curves as follows:

\[
\gamma = \Gamma | [0, 1], \quad u(s) \text{ for } 0 \leq s \leq 1 \\
\kappa = \Gamma | [1, 2], \quad u(2 - s) \text{ for } 0 \leq s \leq 1 
\]

The orbit \( \{ \Psi_t(u_1) \mid 0 \leq t \leq T_1 \} \) forms the long boundary of the propellers \( P_\gamma \) and \( P_\kappa \) generated by the \( \Psi_t \)-flow of these curves. Then \( P_\Gamma \) is viewed as the gluing of \( P_\gamma \) and \( P_\kappa \) along the long boundary, which forms a “zipper” joining the two surfaces together, hence the notation “double propeller” for \( P_\Gamma \). Note that the length of the zipper tends to infinity as \( r(u_1) \to 2 \).

![Figure 29. The curves \( \Gamma = \gamma \cup \kappa \) and \( \Lambda = \lambda \cup \chi \) in \( \partial h^{-1} \mathcal{W} \)](image)

We comment on the details of Figure 29. Comparing Figure 29 with Figure 23, the \( \gamma \) and \( \lambda \) curves are the first half arcs in \( \Gamma \) and \( \Lambda \) (first in the \( S^1 \) direction), while \( \kappa \) and \( \chi \) are the second half arcs in \( \Gamma \) and \( \Lambda \), respectively.

If \( \epsilon = 0 \), define two infinite propellers \( P_\gamma \) and \( P_\kappa \) as in Definition 11, and then define \( P_\Gamma = P_\gamma \cup P_\kappa \), where the \( \Psi_t \)-orbit \( Z_\gamma \) of the midpoint \( u_1 \), defined as in (39), is again common to both \( P_\gamma \) and \( P_\kappa \), and \( P_\Gamma \) is viewed as the gluing of the two propellers along an “infinite zipper”.
DEFINITION 13.1. Let \( \Gamma \) be as above with \( r(u_1) = 2 \). Let \( \gamma^\epsilon \) and \( \kappa^\epsilon \) for \( 0 < \epsilon \leq 1 \) be the curves as defined in (40). The infinite double propeller is the union:
\[
P_\Gamma = Z_\gamma \cup \bigcup_{\epsilon > 0} \{ P_\gamma^\epsilon \cup P_\kappa^\epsilon \}
\]

Observe that \( T_\Gamma = P_\Gamma \cup R \) as in Proposition 11.2.

We next apply these ideas to the study of the invariant set \( \mathcal{M}_0 \). Recall the curves \( \gamma \) and \( \lambda \) defined by (46) were obtained from the intersection of the Reeb cylinder \( R \) in \( W \) with the entry faces \( L_1^- \) and \( L_2^- \). Now consider the intersections of the full cylinder \( C \equiv \{ r = 2 \} \) with the entry faces \( L_1^- \) and \( L_2^- \), which yields the curves:
\[
\Gamma' = C \cap L_1^- \subset W, \quad \Gamma = \sigma_1^{-1}(\Gamma') \subset L_1^- \\
\Lambda' = C \cap L_2^- \subset W, \quad \Lambda = \sigma_2^{-1}(\Lambda') \subset L_2^-
\]

Hypothesis 12.1 implies that the curves \( \Gamma \) and \( \Lambda \) are topologically transverse to the cylinders \( \{ r = \text{const.} \} \), except at their middle points, where they are tangent to the cylinder \( C \), as in Figure 29. The endpoints of each of the curves \( \Gamma \) and \( \Lambda \) have \( r \)-coordinates equal to 3. For the curves \( \gamma' \) and \( \chi' \) as defined in Section 12 note that \( \gamma' = \Gamma' \cap R \) and \( \chi' = \Lambda' \cap R \). Also, set
\[
\kappa = \sigma_1^{-1}(\Gamma' \cap \{ z \leq -1 \}) \quad \text{and} \quad \chi = \sigma_2^{-1}(\Lambda' \cap \{ z \geq 1 \}).
\]
The graphs of the curves \( \Gamma, \gamma, \kappa \) near the special point \( \tau^{-1}(p_1^-) \in L_1^- \) are illustrated in Figure 29 as well as the graphs of \( \Lambda, \chi \) near the special point \( \tau^{-1}(p_2^-) \in L_2^- \).

Let \( P_\Gamma \) and \( P_\Lambda \) be the infinite double propellers associated to these curves by (57). The curves \( \Gamma \) and \( \Lambda \) are disjoint in \( \partial_K W \), thus the infinite double propellers \( P_\Gamma \) and \( P_\Lambda \) are disjoint in \( W \). Consider then the notched infinite double propellers,
\[
P_\Gamma' = P_\Gamma \cap W' \quad \text{and} \quad P_\Lambda' = P_\Lambda \cap W'.
\]

LEMMA 13.2. The notched propellers \( P_\Gamma' \) and \( P_\Lambda' \) are tangent to \( C' = C \cap W' \) along the \( W \)-orbit of the special points \( \tau^{-1}(p_1^+) \in L_1^+ \) and \( \tau^{-1}(p_2^+) \in L_2^+ \), respectively.

Proof. The curves \( \Gamma, \Gamma', \Lambda \) and \( \Lambda' \) are tangent to the cylinder \( C' \) at their middle points that are the points \( \tau^{-1}(p_1^+) \) and \( \tau^{-1}(p_2^+) \), respectively. Hence \( P_\Gamma' \) and \( P_\Lambda' \) are tangent to \( C' \) along the \( W \)-orbits of these points. \( \square \)

The bases of the propellers \( P_\Gamma' \) and \( P_\Lambda' \) are then “glued” to the notched cylinder \( C' \) using the maps \( \sigma_1 \) and \( \sigma_2 \), respectively. This adds to the notched cylinder \( C' \) two infinitely long “tubes with notched holes” that wrap around \( C' \), accumulating on the notched Reeb cylinder \( R' \). Moreover, the tubes are tangent to \( C' \) along the \( W \)-arcs of the special orbits that are in \( C' - R' \).

Consider the \( \Phi_t \)-flow of the image \( \tau(C') \subset K \):
\[
\mathcal{M}_0 = \{ \Phi_t(\tau(C')) \mid -\infty < t < \infty \}.
\]
The level function \( n_0 \) introduced in Proposition 10.1 extends to a well-defined function on \( \mathcal{M}_0 \), using the same method of proof, where \( \tau(C') \) has level 0 by definition. Thus, \( \mathcal{M}_0 \) can be decomposed into its level sets:
\[
\mathcal{M}^n_0 = \{ x \in \mathcal{M}_0 \mid n_0(x) \leq n \}, \quad n = 0, 1, 2, \ldots
\]

Then \( \mathcal{M}_0^1 = \tau(C' \cup \overline{\Gamma} \cup \overline{\Lambda}) \) as defined above. The set \( \mathcal{M}_0^1 \) is obtained by attaching to the notches of \( \tau(C') \) the double infinite propellers \( \tau(P'_\Gamma) \) and \( \tau(P'_\Lambda) \), as well as part of the boundaries of their notches. In complete analogy with the construction of \( \mathcal{M}_0 \), repeat this process recursively for each family of notches, to obtain an embedded surface \( \mathcal{M}_0 \subset K \). Note that \( \mathcal{M}_0 \subset \mathcal{M}_0^1 \).

Next, we use the labeling system for \( \mathcal{M}_0 \) to describe the intersection of \( \mathcal{M}_0 \) with \( E_1 \) and \( E_2 \). For this section, we keep the assumption \( b = 0 \) that will be dropped in Section 15. Recall the notation convention of Remark 12.7. The infinite sequence of points \( p'(i_0; \ell_1, \ell_1) \) for \( \ell_1 \geq 0 \) introduced in Section 12 all lie on...
the $\mathcal{W}$-orbits of the points $\tau^{-1}(p_{10}^\pm)$ which are contained in the open “half-cylinders”, either $\mathcal{C} \cap \{z < -1\}$ or $\mathcal{C} \cap \{z > 1\}$.

The $\mathcal{K}$-orbits of the points $\tau(p(i_0;i_1,\ell_1))$ for $i_0, i_1 = 1, 2$ and $\ell_1 \geq 0$, yield the families of points labeled as $p(i_0;i_1,\ell_1;\ell_2;\cdots;i_n,\ell_n)$, which are the basepoints for the curves introduced in Section 12. The double propellers also share these same basepoints, the basepoint of a double propeller is the “middle” point in the curve generating it. We adopt the same notation system.

For $i = 1, 2$, apply $\sigma_i^{-1}$ to the intersections of $P_1$ and $P_\Lambda$ with the faces $L_i^-$ to obtain, in $L_1^- \cup L_2^- \subset \partial_+^h \mathcal{W}$, four countable collections of curves, labeled in a manner corresponding to that used for the curves $\gamma(i,\ell)$ and $\lambda(i,\ell)$ in (54). For $\ell \geq 0$, we set:

- $\Gamma(1,\ell) = \gamma(1,\ell) \cup \kappa(1,\ell) \subseteq L_1^-$, based at $p(1;1,\ell)$ and corresponding to $P_1$;
- $\Gamma(2,\ell) = \gamma(2,\ell) \cup \kappa(2,\ell) \subseteq L_2^-$, based at $p(1;2,\ell)$ and corresponding to $P_1$;
- $\Lambda(1,\ell) = \lambda(1,\ell) \cup \chi(1,\ell) \subseteq L_1^-$, based at $p(2;1,\ell)$ and corresponding to $P_\Lambda$;
- $\Lambda(2,\ell) = \lambda(2,\ell) \cup \chi(2,\ell) \subseteq L_2^-$, based at $p(2;2,\ell)$ and corresponding to $P_\Lambda$.

The endpoints of each of the curves $\Gamma(i,\ell)$ and $\Lambda(j,\ell)$ are contained in the boundary of $\partial_+^h \mathcal{W}$, while the midpoints are endpoints for $\gamma(i,\ell)$ and $\kappa(i,\ell)$, or $\lambda(j,\ell)$ and $\chi(j,\ell)$, accordingly.

Note that the curves $\Gamma(i,\ell)$ and $\Lambda'(j,\ell)$ in the faces $L_i^-$ are the result of applying the $\Psi_r$-flow to the curves $\Gamma$ and $\Lambda$. We thus obtain four countable collections of double propellers $P_{\Gamma(i,\ell)}$ and $P_{\Lambda(j,\ell)}$, for $i, j = 1, 2$, and notched double propellers $P'_{\Gamma(i,\ell)}$ and $P'_{\Lambda(j,\ell)}$.

As in Section 12, this creation and labeling of double propellers proceeds recursively, though for levels $n \geq 2$, the propellers obtained are finite as the base curves are contained in the region $r > 2$. There is a nuance that arises with the construction of the corresponding double propellers, however. The curves $\kappa(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in L_{i_n}^-$ and $\gamma(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in L_{i_n}^-$ do not satisfy the radial monotonicity hypothesis. In particular, their intersection point, the “midpoint” $u_1$ will not be the point where $r(u_1)$ is minimal. However, the $\kappa$ and $\gamma$ curves are endpoint isotopic to a curve satisfying the transversality condition, hence the conclusion that the corresponding curve $\Gamma$ separates the region $L_i^-$ will remain true, so that the double propeller $P_{\Gamma(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)}$ is isotopic to a standard double propeller, hence will separate $\mathcal{W}$ into two connected components as well. Similar remarks also hold for the double propeller $P_{\Lambda(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)}$, and we label the base curves resulting from the $\Phi_r$-flow:

- $\gamma(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in \Gamma(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \subseteq L_{i_n}^-$, which is based at $p(1;i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)$;
- $\kappa(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in \Gamma(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \subseteq L_{i_n}^-$, which is based at $p(1;i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)$;
- $\lambda(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in \Lambda(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \subseteq L_{i_n}^-$, which is based at $p(2;i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)$;
- $\chi(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \in \Lambda(i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n) \subseteq L_{i_n}^-$, which is based at $p(2;i_1,\ell_1;i_2,\ell_2;\cdots;i_n,\ell_n)$.

The shape of $\kappa$, $\gamma$, $\chi$ and $\lambda$ curves will be important in latter sections, and analyzed in Section 18.

There is a tangency relation between double propellers with consecutive levels. Consider the curve $\Gamma \subseteq L_i^-$ and the curves $\Gamma(1,\ell) \subseteq L_i^-$. The base point $p'(1;1,\ell)$ of $\Gamma'(1,\ell) \subseteq L_i^-$ has radius equal to 2 and thus belongs to $\mathcal{C} \cap L_i^-$. Then $p(1;1,\ell)$ is a point in $\kappa$ and every $\Gamma(1,\ell)$ curve is tangent to $\kappa$ at $p(1;1,\ell)$. Analogously,

- $\Lambda(1,\ell)$ is tangent to $\kappa$ at $p(2;1,\ell)$;
- $\Gamma(2,\ell)$ is tangent to $\chi$ at $p(1;2,\ell)$;
- $\Lambda(2,\ell)$ is tangent to $\chi$ at $p(2;2,\ell)$.

Thus the level 2 propellers $P_{\Gamma(i_1,\ell_1)}$ and $P_{\Lambda(i_1,\ell_1)}$ are tangent along the $\mathcal{W}$-orbit of $p(1;i_1,\ell_1)$ and $p(2;i_1,\ell_1)$, respectively, to the level 1 propeller $P_\Gamma$ if $i_1 = 1$ and $P_\Lambda$ if $i_1 = 2$. This is illustrated in Figure 30 below.
In general, a Γ or Λ curve at level \( n \) is tangent to a κ or χ curve at level \( n - 1 \), more precisely:

- **Γ(1; ℓ₁,ℓ₂; i₄,ℓ₄; ···; iₙ,ℓₙ) \( \subset L_{iₙ}^- \) is tangent to κ(1; i₂,ℓ₂; ···; iₙ,ℓₙ) at \( p(1; 1; i₂,ℓ₂; ···; iₙ,ℓₙ) \);
- **Γ(2; ℓ₁,ℓ₂; i₄,ℓ₄; ···; iₙ,ℓₙ) \( \subset L_{iₙ}^- \) is tangent to κ(2; i₂,ℓ₂; ···; iₙ,ℓₙ) at \( p(2; 1; i₂,ℓ₂; ···; iₙ,ℓₙ) \);
- **Λ(1; ℓ₁,ℓ₂; i₄,ℓ₄; ···; iₙ,ℓₙ) \( \subset L_{iₙ}^- \) is tangent to κ(1; i₂,ℓ₂; ···; iₙ,ℓₙ) at \( p(2; 2; i₂,ℓ₂; ···; iₙ,ℓₙ) \);
- **Λ(2; ℓ₁,ℓ₂; i₄,ℓ₄; ···; iₙ,ℓₙ) \( \subset L_{iₙ}^- \) is tangent to κ(2; i₂,ℓ₂; ···; iₙ,ℓₙ) at \( p(2; 2; i₂,ℓ₂; ···; iₙ,ℓₙ) \).

Recall that the points \( p(i₀; i₁; ℓ₁) \) converge as \( ℓ₁ \to ∞ \) to \( p(i₁) \) as described in Section 12. This type of convergence is repeated at any level. The level \( n \) points \( p(i₀; i₁, ℓ₁; i₂, ℓ₂; ···; iₙ, ℓₙ) \) that belong to the curve κ(1; i₂,ℓ₂; ···; iₙ,ℓₙ) if \( i₁ = 1 \) and to the curve χ(1; i₂,ℓ₂; ···; iₙ,ℓₙ) if \( i₁ = 2 \), converge to \( p(i₁, ℓ₁; i₂, ℓ₂; ···; iₙ, ℓₙ) \) as \( ℓ₁ \to ∞ \). Observe that the last point is the base point of the κ or χ curve.

We next consider the intersections of the double propeller surfaces with the rectangle \( R₀ \). Note that the \( Ψ₄ \)-flow of a parabolic curve \( Γ \subset \{ r > 2 \} \cap \partial^− \mathcal{W} \) with endpoints in \( \{ r = 3 \} \) forms a compact surface in \( \mathcal{W} \) with boundary contained in \( \partial^\mathcal{W} \), and the vector field \( \mathcal{W} \) is tangent to this surface. Thus, its intersections with the rectangle \( R₀ \) are always transverse, so must be a finite union of closed curves. Moreover, the \( z \)-symmetry of the vector field \( \mathcal{W} \) implies these intersections are symmetric with respect to the horizontal line \( \{ z = 0 \} \cap R₀ \).
In the case of the parabolic curves \( \Gamma = \gamma \cup \kappa \subset L^1_1 \) and \( \Lambda = \lambda \cup \chi \subset L^1_2 \), the intersections of the propellers generated by the curves \( \gamma \) and \( \kappa \) with the set \( R_0 \) yields a family of arcs, as illustrated in Figure 20. Thus, the intersections with \( R_0 \) of the double propeller formed from their \( \Psi_t \)-flows yields a family of “thin circles”, as illustrated by Figure 31. We call these curves “ellipses” for short.

First, introduce the following line segments contained in the intersection illustrated by Figure 31. We call these curves “ellipses” for short.

\[
I = \{(2, \pi, z) \mid -1 \leq z \leq 1\}, J_0 = \{(2, \pi, z) \mid -2 \leq z \leq -1\}, K_0 = \{(2, \pi, z) \mid 1 \leq z \leq 2\}.
\]

The endpoints of the interval \( I_0 \) are the two special points, \( \omega_i = \mathcal{O}_i \cap R_0 \), for \( i = 1, 2 \). The arcs \( N_0 \) and \( M_0 \) are connected curves in \( R_0 \) which contain these special points as midpoints.

Proposition 6.7 implies that the \( \Phi_t \)-flow of \( I_0 \) contains the “notched” Reeb cylinder \( \tau(\mathcal{R}') \), thus the \( \Phi_t \)-flow of \( I_0 \) equals \( \mathcal{R}_0 \). The \( \Phi_t \)-flow of \( C_0 \) contains the double propellers.

The forward \( \Phi_t \)-flow of \( N_0 \) intersects \( E_1 \) in \( \tau(\Gamma) \) and generates the embedded double propeller \( \tau(P_1^t) \subset \mathcal{K} \). The intersection \( \tau(P_1^t) \cap R_0 \) is a countable family of closed curves labeled as \( \Gamma_0(\ell) \) that are tangent to \( J_0 \) along the forward \( \Phi_t \)-orbit of \( \omega_1 \) and to \( K_0 \) along the backward \( \Phi_t \)-orbit of \( \omega_1 \).

The forward \( \Phi_t \)-flow of \( M_0 \) intersects \( E_2 \) in \( \tau(\Lambda) \) and generates the embedded double propeller \( \tau(P_\Lambda^t) \subset \mathcal{K} \). The intersection \( \tau(P_\Lambda^t) \cap R_0 \) is a countable family of closed curves \( \Lambda_0(\ell) \subset R_0 \) that are tangent to \( J_0 \) along the forward \( \Phi_t \)-orbit of \( \omega_2 \) and to \( K_0 \) along the backward \( \Phi_t \)-orbit of \( \omega_2 \).

Note that in the above and later, the subscript “0” indicates by convention that a curve is in \( R_0 \), and so may be considered as belonging to \( \mathbb{W} \) or \( \mathbb{K} \), according to the context.

The indexing \( \ell \) of the closed curves \( \Gamma_0(\ell) \) and \( \Lambda_0(\ell) \) and their images under the \( \Phi_t \)-flow, involves a subtlety which is analogous to that arising in the proof of Proposition 9.15. It is possible that some of the resulting curves from this flow will intersect in forward time \( E_1 \) and \( E_2 \), before returning to \( R_0 \). Thus, the labeling for curves in these faces as constructed in Section 11 and above, may include some which do not intersect \( E_1 \cup E_2 \) before returning to \( R_0 \). This is the motivation for the following labeling convention.

Let \( \Gamma_0(a) \), for \( a \leq 0 \), denote the first such curve \( \Gamma_0(\ell) \) that intersects \( R_0 \), whose intersection with the vertical line \( \{r = 2\} \subset R_0 \) is composed of the two vertex points \( p_0(1; 1, a) \) and \( p_0(1; 2, a) \).

Let \( \Gamma_0(0) \) be the first such curve for which the \( \mathcal{K} \)-orbit of its lower vertex point \( p_0(1; 1, 0) \) intersects \( E_1 \) before intersecting \( R_0 \) again. We assume, without loss of generality, that the \( \mathcal{K} \)-orbit of \( p_0(1; 2, 0) \) intersects \( E_2 \) before intersecting \( R_0 \) again. This symmetry assumption simplifies the labeling system.

**Remark 13.3.** The indexing of the curves starts with a value of \( \ell = a \), possibly negative, such that for \( a \leq \ell < 0 \), the \( \mathcal{K} \)-orbit of the vertices of the curves \( \Gamma_0(\ell) \) do not intersect \( E_1 \cup E_2 \) in forward time, before returning to \( R_0 \). The number of such non-positive indices \( \ell \) is finite, or might be zero. In the latter case, the indexing starts at \( \ell = 0 \), and it signifies that the forward \( \Phi_t \)-flow of the vertices of \( \Gamma_0(\ell) \) intersects the entry regions \( E_1 \) or \( E_2 \) in curves \( \Gamma(1, \ell) \) or \( \Gamma(2, \ell) \), respectively, before intersecting \( R_0 \) again. Similar comments apply for the indexing of the \( \Lambda_0 \) curves.

Observe that \( a \leq b \leq 0 \) for \( b \) as introduced in Section 12. As we assume that \( b = 0 \), then for \( a \leq \ell < 0 \), the \( \Phi_t \)-orbit segment starting at any point of \( \Gamma_0(\ell) \) and ending at the corresponding point of \( \Gamma_0(\ell + 1) \) will not contain transition points.
Next consider the embedded propellers $\tau(P_{\Gamma(1,i,\ell)})$ which are the image under $\tau$ of compact surfaces traversing $\mathbb{W}$ from the bottom face $\partial^-\mathbb{W}$ to the top face $\partial^+\mathbb{W}$. They intersect $\mathcal{L}_1$ and $\mathcal{L}_2$ in finite families of closed curves, denoted by $\Gamma'(1,\ell_1;1,\ell)$ and $\Gamma'(1,\ell_1;2,\ell)$, and whose inverse image in $L^-_i$ is denoted by $\Gamma(1,\ell_1;i,\ell_2)$, for $i = 1, 2$ and $\ell_2 \geq 0$. We form the corresponding finite families of closed curves in $R_0$ denoted by $\Gamma_0(1,\ell_1;i,\ell_2)$, whose positive $\Phi_0$-flows intersect $E_i$ in the curves $\lambda(\Gamma(1,\ell_1;i,\ell_2))$ for $i = 1, 2$. The index $i$ signifies whether we follow the $\Phi_0$-flow of the curve $\Gamma_0(1,\ell_1;i,\ell_2)$ in the region $\{z < 0\}$ to the surface $E_1$, or we follow the $\Phi_0$-flow into the region $\{z > 0\}$ to the surface $E_2$.

Similarly, the embedded propellers $\tau(P_{\Gamma(2,\ell,i)})$ intersect $R_0$ in finite families of closed curves $\Gamma_0(2,\ell_1;i,\ell_2)$, as illustrated in Figure 32. The positive $\Phi_0$-flows of these curves in $R_0$ intersects $E_1$ and $E_2$ in curves denoted by $\tau(\Gamma(2,\ell_1;1,\ell_2))$ and $\tau(\Gamma(2,\ell_1;2,\ell_2))$ for $\ell_2 \geq 0$, respectively. These curves define in turn, propellers that intersect $R_0$ along closed curves, which are recursively defined as:

1. $\Gamma_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n) \subset R_0$ containing the “vertex points” $p_0(1;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ for $i_n = 1, 2$ and with level $n$;
2. $\lambda_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n) \subset R_0$ containing the “vertex points” $p_0(2;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ for $i_n = 1, 2$ and with level $n$.

The points $p_0(i_0;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ correspond to the points $p(i_0;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ in the same manner as the curves $\Gamma_0(i_1,\ell_1;i_2,\ell_2;\cdots; \ell_n)$ correspond to both $\Gamma(i_1,\ell_1;i_2,\ell_2;\cdots; 1,\ell_n)$ and $\Gamma(i_1,\ell_1;i_2,\ell_2;\cdots; 2,\ell_n)$.

We also introduce the curves in $R_0$:

1. $\lambda_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n)$ and $\chi_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n)$ contained in $\Gamma_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n) \subset R_0$, with $p_0(1;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ as common boundary points for $i_n = 1, 2$;
2. $\lambda_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n)$ and $\chi_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n)$ contained in $\lambda_0(i_1,\ell_1;i_2,\ell_2;\cdots; i_{n-1},\ell_{n-1};\ell_n) \subset R_0$, with $p_0(2;i_1,\ell_1;i_2,\ell_2;\cdots; i_n,\ell_n)$ as common boundary points for $i_n = 1, 2$.

**Remark 13.4.** For points of level at least 2, the number of positive indices $\ell_n$ such that $p(i_0;i_1,\ell_1;\cdots; i_n,\ell_n)$ exists is greater or equal to the number of indices such that the point $p(i_0;i_1,\ell_1;\cdots; i_n,\ell_n)$ exists, since the curves in the intersection of propellers at level at least 2 get shorter as we approach the tip of the propeller and might not intersect the insertions.

The $\gamma_0$-curves and $\lambda_0$-curves are in the $\Phi_0$-flow of $I_0$, while the $\kappa_0$ and $\chi_0$ curves are in the $\Phi_0$-flow of $J_0$ and $K_0$, respectively. Each $\Gamma_0(\ell)$ is tangent to $J_0$ at $p_0(1;1,\ell)$ and to $K_0$ at $p_0(1;2,\ell)$. Then, we obtain that the $\Gamma_0$ curves at level $n$ are tangent to a $\kappa_0$ or a $\chi_0$ curve of level $n - 1$. Likewise, each $\lambda_0$ curve at level $n$ is tangent to a $\kappa_0$ and a $\chi_0$ curve of level $n - 1$, as for curves in $L^-_i$.

Observe that this tangency relation implies that the curves $\Gamma_0(1,\ell_1;i,\ell_2)$ and $\lambda_0(1,\ell_1;i,\ell_2)$ are tangent to $\kappa_0(\ell_2)$ at their vertex points. Hence $\Gamma_0(1,\ell_1;i,\ell_2)$ and $\lambda_0(1,\ell_1;i,\ell_2)$ are inside the region bounded by $\Gamma_0(\ell_2)$, for any $\ell_1 \geq a$. Likewise, $\Gamma_0(2,\ell_1;i,\ell_2)$ and $\lambda_0(2,\ell_1;i,\ell_2)$ are inside the region bounded by $\lambda_0(\ell_2)$, for any $\ell_1 \geq a$. Iterating this relation we have that:

- the curves $\Gamma_0(1,\ell_1;i_2,\ell_2;\cdots; \ell_n)$ and $\lambda_0(1,\ell_1;i_2,\ell_2;\cdots; \ell_n)$ are tangent at their vertex points to $\kappa_0(i_2,\ell_2;\cdots; \ell_n)$ and lie inside the region bounded by $\Gamma_0(i_2,\ell_2;\cdots; \ell_n)$;
- the curves $\Gamma_0(2,\ell_1;i_2,\ell_2;\cdots; \ell_n)$ and $\lambda_0(2,\ell_1;i_2,\ell_2;\cdots; \ell_n)$ are tangent at their vertex points to $\chi_0(i_2,\ell_2;\cdots; \ell_n)$ and lie inside the region bounded by $\lambda_0(i_2,\ell_2;\cdots; \ell_n)$.

Thus the $\Gamma_0$ and $\lambda_0$ curves form families of nested ellipses. By construction, inside the region bounded by $\Gamma_0(\ell_n)$ are all the $\Gamma_0$ and $\lambda_0$ curves whose first $i$-index is equal to 1 and whose last $\ell$-index is equal to $\ell_n$. This relation, up to level 3, is illustrated in Figure 32.
LEMMA 13.5. For each family of curves defined by a member of \( \{ \Gamma_0, \gamma_0, \kappa_0, \Lambda_0, \lambda_0, \chi_0 \} \), and for each \( \varphi \in G_K^* \), the action of \( \varphi \) maps the family of curves to a subset of itself.

For \( n > 1 \), recall that the last index \( \ell_n \) for a curve \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \) is bounded above, with the bound depending on the previous indices, and by abuse of notation, let \( \ell_n' = \ell_n(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}) \) denote its maximum value. Recall that there is no restriction on the first index, so \( \ell_1' = \infty \).

Proposition 9.9 implies that each of the sets of points \( \{ p_0(1; \cdots ) \} \) and \( \{ p_0(2; \cdots ) \} \) is invariant, thus the action on these points determines which curve in each of these families is mapped to which curve, and correspondingly, the action on the curves determines the action on these vertices.

We first analyze the action of the map \( \psi \). Recall from Section 9 that the map \( \psi \) is obtained from the return map of the Wilson flow to \( R_0 \), hence \( \psi \) preserves the level function \( n_0 \). The intervals \( I_0, J_0 \) and \( K_0 \) are mapped to themselves, with fixed-points \( \omega_i \), for \( i = 1, 2 \). Consider the open sets in the domain of \( \psi \) defined by \( U_+ \subset R_0 \cap \{ r \geq 2, z > 0 \} \) and \( U_- \subset R_0 \cap \{ r \geq 2, z < 0 \} \). The set \( U_- \) further decomposes into open sets defined by the range of \( \psi \),

\[
\psi: U_- \rightarrow U_- , \quad \psi: U_+ \rightarrow R_0 \cap \{ r \geq 2, z \geq 0 \},
\]

as illustrated in Figure 33.

The following is a direct consequence of our labeling system:

LEMMA 13.6. The action \( \psi \) on the \( \Gamma_0 \) curves is as follows:

1. The map \( \psi : U_- \rightarrow U_- \), sends a subset of the curve \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \) to a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n+1) \), for \( 0 \leq \ell_n < \ell_n' \). For \( n = 1 \), this operation is always allowed.

2. The map \( \psi : U_+ \rightarrow R_0 \cap \{ z \geq 0 \} \), sends a subset of the curve \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \) to a subset of itself.
(3) The map \( \psi : U_+ \to R_0 \cap \{ z \geq 0 \} \), sends a subset of the curve \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \) to a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n - 1) \). For every \( n \geq 1 \), the index \( \ell_n \) is bounded below, hence the map \( \psi \) can only be applied to such a curve a finite number of times.

The action on the other families of curves is analogous, but it is slightly different on the base points. The difference is made explicit in Lemma 13.9.1(b).

Next, we analyze the action of the maps \( \phi_i^+ : U_{\phi_i^+} \to R_0 \) for \( i = 1, 2 \). The domain \( U_{\phi_i^+} \) consists of points \( x \in R_0 \) whose forward K-orbit intercepts the face \( E_i \) and then continues on to intercept \( R_0 \) again, hence the level is increased by one under these maps. Hypothesis (K3) on the embeddings \( \sigma_i \) implies that their domains \( U_{\phi_i^+} \subset R_0 \) satisfy

\[
U_{\phi_1^+} \subset R_0 \cap \{ z < 0 \} \ , \ U_{\phi_2^+} \subset R_0 \cap \{ z > 0 \}
\]

and that their ranges satisfy

\[
\phi_1^+(U_{\phi_1^+}) = V_{\phi_1^+} \subset R_0 \cap \{ z < 0 \} \ , \ \phi_2^+(U_{\phi_2^+}) = V_{\phi_2^+} \subset R_0 \cap \{ z > 0 \},
\]

as represented in Figure 17. Then (67) and the definition of the indexing system yields:

**Lemma 13.7.** For \( i = 1, 2 \), the map \( \phi_i^+ \) sends a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \) for \( \ell_n \geq 0 \) to a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; i, \ell_n; a) \) where \( a \leq 0 \) is the first index such that the curve \( \Gamma_0(a) \) exists.

Note that \( \phi_i^+ \) sends any point in \( U_{\phi_i^+} \cap \{ r \geq 2 \} \) to a point that is contained in the closed region bounded by the curve \( \Gamma_0(a) \) if \( i = 1 \) and by \( \Lambda_0(a) \) if \( i = 2 \).

We comment on Figure 34 it is useful to compare it with Figure 28. The horizontal upper band represents the Reeb cylinder \( \tau(R') \). The transverse lines to the cylinder and propellers represent their intersections with the rectangle \( R_0 \). Since only \( \tau(P_0') \) and its ramifications are illustrated, these lines correspond to \( \gamma_0 \)-curves.

The generator \( \psi \) preserves level, hence it moves points along propellers. The points in \( \tau(R') \cap R_0 \) are \( \psi \)-invariant. For points in the left side boundary of \( \tau(P_i') \), the action of \( \psi \) pushes them downwards to the following \( \gamma_0 \)-curve, while for points in the right side boundary \( \tau(P_i') \) it moves points upwards. The maps \( \phi_i^+ \) add 1 to the level, so they correspond to jumping to the first curve at higher level. For example, for the curve \( \gamma_0(0) \), \( \phi_1^+ \) moves points to \( \gamma_0(1, 0; 0) \) and \( \phi_2^+ \) moves points to \( \gamma_0(2, 0; 0) \). Observe that the meaning of “first” curve is in the direction of the flow, that runs in opposite directions near the boundaries of \( \tau(P_i') \). The actions of \( \phi_i^- \) are also illustrated.
The action of a general element $\varphi \in G_K^*$ on a curve in one of the families $\{\Gamma_0, \gamma_0, \kappa_0, \Lambda_0, \lambda_0, \chi_0\}$, can be quite complicated and will be considered further in Section 21. For now, consider the simplest case of iterations of the map $\phi_i^+$. The image $\phi_i^+(N_0 \cap U_{\phi_i^+}) \subset R_0$ is a parabolic curve, twisting upwards as illustrated on the right side of Figure 35. If the image curve $\phi_i^+(N_0 \cap U_{\phi_i^+})$ is again (partially) contained in the domain of $\phi_i^+$, then we can consider its (restricted) image under $\phi_i^+$ and repeat this process inductively as long as it is defined. This yields a family of parabolic curves, as illustrated on the right side of Figure 35 which shows the image $\phi_i^+(I_0 \cap U_{\phi_i^+})$ on the left-hand-side and three iterations of this map applied to $N_0$ on the right-hand-side.

Finally, we analyze the action of the maps $\phi_i^- : U_{\phi_i^-} \to R_0$ for $i = 1, 2$, which are defined using the $\Phi_t$-flow. The domain $U_{\phi_i^-}$ consists of points $x \in R_0$ whose forward $K$-orbit intersects the face $S_i$ and then continues...
on to intercept \( R_0 \) again. Hence, the level is decreased by 1 under these maps, and \( U_{\phi_i^+} \subset R_0 \cap \{ z > 0 \} \) for \( i = 1, 2 \).

**Lemma 13.8.** For \( i = 1, 2 \) and \( n \geq 2 \), \((\phi_i^+)^{-1}\) maps a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_n-1, \ell_{n-1} ; \ell_n) \) to a subset of \( \Gamma_0(i_1, \ell_1; \cdots ; i_n-1, \ell_{n-1} ; \ell_n) \), where \( a \) is defined as in Lemma 13.7. Hence, \( \phi_i^+ \) is only defined on the curves \( \Gamma_0(i_1, \ell_1; \cdots ; i_n, \ell_n) \).

We now comment on the behavior of the points \( p_0(i_0; i_1, \ell_1; \cdots ; i_n, \ell_n) \). The points \( \phi_i(i_0; i_1, \ell_1) \) are in \( \mathcal{L}_1^+ \) for \( \ell \geq 0 \), with \( r'(i_0; i_1, \ell_1) = 2 \) and \( z'(i_0; i_1, \ell_1) < -1 \). Thus, \( p(i_0; i_1, \ell_1) \in \kappa \subset \Gamma \subset \mathcal{L}_1^- \) and \( p_0(i_0; i_1, \ell_1) \in J_0 \). Since \( p_0(i_0; i_1, \ell_1) \) belongs to \( \mathcal{U}_1 \) as \( \ell \to \infty \), \( \phi_i^+ \) are in \( \mathcal{L}_1^+ \). Hence, \( \phi_i^+ \) is only defined for \( \ell \) large enough, if \( \ell \) belongs to \( \mathcal{U}_1 \).

If \( p_0(i_0; i_1, \ell_1, 2; a) \in U_{\phi_i^+} \), Lemma 13.7 implies that \( \phi_i^+(p_0(i_0; i_1, \ell_1, 1, a)) \) belongs to the curve \( \kappa_0(a) \) in \( \{ z \leq 0 \} \). Thus the points \( p_0(i_0; i_1, \ell_1, 1, a) \) accumulate on \( p_0(1; 1, a) = \phi_i^+(\omega_i) \) for \( \ell_1 \to \infty \). Observe that \( p_0(1; 1, a) \) is the vertex point of the curve \( \kappa_0(a) \).

Analogously, the points \( p_0(i_0; i_1) \) belong to the curve \( \kappa_0(a) \) and accumulate on \( p_0(1; 2, a) \), the other vertex point of \( \kappa_0(a) \), as \( \ell_1 \to \infty \). The points \( p_0(i_0; 2, \ell_1, 2; a) \) belong to the curve \( \chi_0(a) \) and accumulate on \( p_0(2; 2, a) \) as \( \ell_1 \to \infty \).

**Lemma 13.9.** The maps \( \psi_i, \phi_i^+ \) and \( \phi_i^2 \) act on \( p_0 \) points as follows:

1. For the map \( \psi \) we have the three following possibilities:
   a. For \( 1 \leq n < \ell_n \), \( \psi : U_1 \to U_0 \) maps \( p_0(i_0; i_1, \ell_1; \cdots ; i_n; \ell_n) \) to \( p_0(i_0; i_1, \ell_1; \cdots ; i_n; \ell_n + 1) \). For \( n = 1 \), this operation is always allowed.
   b. \( \psi : U_1 \to R_0 \cap \{ z \geq 0 \} \) maps \( p_0(i_0; i_1, \ell_1; \cdots ; i_n, \ell_n) \) to \( p_0(i_0; i_1, \ell_1; \cdots ; i_n, \ell_n) \).

2. \( \phi_1^+ \) maps a point \( p_0(i_0; i_1, \ell_1; \cdots ; i_n, \ell_n) \) in its domain to \( p_0(i_0; i_1, \ell_1; \cdots ; i_n, \ell_n + 1, a) \).
3. \( \phi_2^+ \) maps a point \( p_0(i_0; i_1, \ell_1; \cdots ; 2, \ell_n) \) in its domain to \( p_0(i_0; i_1, \ell_1; \cdots ; 2, \ell_n, a) \).

We have the following consequences of the above results.

**Lemma 13.10.** Every point \( p_0(i_0; i_1; \ell_1; \cdots ; i_n, \ell_n) \) is an accumulation point of the set of \( p_0 \) points.

**Proof.** The points \( p_0(i_0; i_1; \ell_1; \cdots ; i_n, \ell_n) \) lie in the curve \( \kappa_0(i_2, \ell_2; \cdots ; i_{n-1}, \ell_{n-2}, \ell_n) \), and as \( \ell_1 \to \infty \) they accumulate on the point \( p_0(1; i_2, \ell_2; \cdots ; i_{n-1}, \ell_{n-2}, i_n, \ell_n) \).

Also, the points \( p_0(i_0; 2, \ell_1; \cdots ; i_n, \ell_n) \) lie in the curve \( \chi_0(i_2, \ell_2; \cdots ; i_{n-1}, \ell_{n-1}, \ell_n) \), and as \( \ell_1 \to \infty \) they accumulate on the point \( p_0(2; i_2, \ell_2; \cdots ; i_{n-1}, \ell_{n-1}, i_n, \ell_n) \).

14. Normal forms and tree structure of \( \mathcal{M}_0 \)

A major theme of this work is to use the pseudogroup \( \mathcal{G}_K \) generated by the map \( \hat{\Phi} \) acting on \( X = R_0 \), as defined in Definition 9.4, to study the dynamics of the flow \( \Phi_t \). The results of Section 13 interpret the local action of \( \mathcal{G}_K \) in terms of the propellers introduced in Section 12. The application of these two concepts associated to \( \Phi_t \) will be made throughout the remaining sections, and many of the results we establish often rely on highly technical arguments, with various nuances. In this section, we pause to give a broader overview of how these concepts, of pseudogroups and propellers, are related. To this end, we introduce a “tree structure” on the space \( \mathcal{M}_0 \) as defined in [34] and illustrated in Figure 28. Then in Proposition 14.3 we give an algebraic “normal form” for elements of the pseudogroup \( \mathcal{G}_K \). These two results are closely related, as we explain
below. Finally, in Proposition 14.5 we estimate the number of normal forms as a function of the word length, and show that this function has subexponential growth. This is an intrinsic property of the flow $\Phi_t$.

We first construct the tree $T_\Phi \subset M_0$. Recall that the level decomposition of $M_0$ in (56) expresses the space as a union of propellers, and each propeller is defined by the $\Psi_t$-flow of a curve segment in the face $\partial_+ W'$. Each propeller then intersects the center annulus $\{z = 0\} = \tau(A)$. There is a nuance in this picture, as each propeller in the decomposition of $M_0$ may give rise to “bubbles” which correspond to double propellers of uniformly bounded complexity attached on the interior of the given propeller, as in (53). This will be discussed in Section 19 and is illustrated in Figure 36.

As they do not influence the dynamics of the flow $\Phi_t$, they do not appear in Figure 36. In the surface $M_0$, the intersection of each propeller with the annulus $\{z = 0\}$ forms an embedded “center line segment”. Define $T'_\Phi = A \cap M_0$ which consists of the union of these embedded line segments. Let $T'_\Phi \subset T_\Phi$ consist of the line segments in simple propellers. The connected tree $T_\Phi$ is formed by adding continuous curve segments in $M_0$ joining the line segments in $T'_\Phi$, as is illustrated in Figure 36.

Define the center line $T = \{z = 0\} \cap R_0$, and set $C_0' = T \cap M_0$ and $C' = M \cap T$. We will show in Proposition 19.4 that $C'$ is a Cantor set, and observe there that it has a decomposition into two disjoint Cantor sets, $C' = C \cup C'$. The points in the dense subset $C_0' = M_0 \cap C_0'$ of $C'$ correspond to the intersections of the double propellers in bubbles with $T$, while the points in the dense subset $C_0 = M_0 \cap C'$ correspond to the intersections of $\gamma_0$ or $\lambda_0$ curves with $T$. The “fat dots” in Figure 36 correspond to the points contained in the set $C_0$, and the lines through the dots represent the intersection with $R_0$.

The basepoint $\omega_0 = T \cap \tau(R')$ is contained in the core annulus $R = \tau(R') \subset M_0$, illustrated in the picture as the top horizontal strip, which lies at level 0. There is one edge containing $\omega_0$, the top horizontal line in Figure 36, which corresponds to $\tau(R' \cap A)$ and defines a loop containing $\omega_0$. Thus, strictly speaking, $T_\Phi$ is a tree provided the loop containing $\omega_0$ is erased.

Recall that the pseudo-group $G_K^*$ denotes the collection of all maps formed by compositions of the maps $\{Id, \phi_1^+ \phi_1^-, \phi_2^-, \phi_2^+ , \psi\}$ and their restrictions to open subsets in their domains. The action of these generators on the endpoints of $\gamma_0$ and $\lambda_0$ curves in $R_0$ formed by the intersection $M_0 \cap R_0$ were discussed in Section 19.

Note that each such curve intersects the line $T$ in a point of $C_0$, and the actions of the generators $\{\psi, \phi_1^+, \phi_2^+\}$ and their inverses have simple interpretations as actions on the vertices of $T_\Phi$. We introduce the notation $\{\tilde{\psi}, \tilde{\phi}_1, \tilde{\phi}_2\}$ for the induced action on vertices. Later, in Section 21, we consider the pseudo-group $G_M$ generated by these actions in detail.

First, the action of $\tilde{\psi}$ fixes the basepoint $\omega_0$, and can be thought of as flowing in a loop around the horizontal line in the core annulus $R'$. The action of $\tilde{\psi}$ on points in $C_0$, corresponding to $\gamma_0$ curves in $R_0$, is determined by the action of $\psi$: $U^- \to U_-$ as described in Lemma 13.6. We have:

$$\tilde{\psi}: \gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \cap T \mapsto \gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n + 1) \cap T.$$

Since $\tilde{\psi}$ does not change the level, we conclude that $\tilde{\psi}$ moves a point in $C_0$ to the “next point” along the line segment in $T'_\Phi$ containing it. Here, “next” means moving in the positive $\theta$ direction along the propeller, hence making one turn around the circle $S = \{r = 2 & z = 0\}$ in $K$. Thus for $\xi \in C_0$ in the domain of the mapping $\tilde{\psi}$, we have $r(\tilde{\psi}(\xi)) < r(\xi)$ if $\xi \neq \omega_0$. The action of the map $\tilde{\psi}$ on the points $\xi \in C_0$ defined by $\lambda_0$ curves is analogous.

We next show that the paths connecting different level points, which were added to the segments in $T'_\Phi$ to form $T_\Phi$, correspond to the actions of the elements $\tilde{\phi}_k$ for $k = 1, 2$, analogous to the action of $\phi_1^+$. Then by Lemma 13.7 we have that:

$$\tilde{\phi}_k: \gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \cap T \mapsto \gamma_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; k, \ell_n; a) \cap T.$$

where $\ell_n \geq 0$ as the curve must intersect the surface $E_k$ in a boundary notch, and $a \leq 0$ is the first index such that the corresponding curve in $R_0$ exists, as explained in Remark 13.3. A similar result holds for the action of $\tilde{\phi}_k$ on $\lambda_0$ curves. Note that both maps $\tilde{\phi}_1$ and $\tilde{\phi}_2$ increase the level function by 1.
Figure 36. $M_0$ with the embedded tree $T_\phi$.

Figure 37. The action of $\phi_k$. 
The map $\overline{\phi}_1$ acts on $\omega_0$ via the insertion $\phi_1^+$ acting on the point $\omega_1 = (2, \pi, -1)$ to yield $p_0(1, 1, a) = \phi_1^+(\omega_1)$ which corresponds to the first vertex $\overline{\phi}_1(\omega_0)$ at level 1. Graphically, the action of $\overline{\phi}_1$ is to "turn the corner" to the right. This results in adding a curved segment to $T_\phi$ between $\omega_0$ and the point $\overline{\phi}_1(\omega_0)$ in the downward propeller.

The map $\overline{\phi}_2$ acts on $\omega_0$ via the insertion $\phi_2^+$ acting on the point $\omega_2 = (2, \pi, 1)$ to yield $p_0(2, 1, a) = \phi_2^+(\omega_2)$ which corresponds to the first vertex $\overline{\phi}_2(\omega_0)$ at level 1. Graphically, the action of $\overline{\phi}_2$ is to "turn the corner" to the left. This results in adding a curved segment to $T_\phi'$ between $\omega_0$ and the point $\overline{\phi}_2(\omega_0)$ in the upward propeller.

Note that the remaining vertices in $T_\phi$ at level 1 which descend the vertical main propeller $\tau(P_\gamma)$ in Figure 36 correspond to the points $\psi^f \circ \overline{\phi}_1(\omega_0)$. The points $\psi^f \circ \overline{\phi}_2(\omega_0)$, also at level 1, ascend on the propeller $\tau(P_\delta)$ above the core annulus, and are not pictured in Figure 36.

The remaining vertices of the tree $T_\phi$ are at level at least 2. The actions of the maps $\{\overline{\psi}, \overline{\phi}_1, \overline{\phi}_2\}$ on these vertices follows the rules above as defined by (68) and (69). The action of $\overline{\psi}$ is translation along the line in $T_\phi''$ containing it, while the actions of the maps $\overline{\phi}_1$ and $\overline{\phi}_2$ turn the corner into the propeller at the next higher level, to the right or left accordingly. Accordingly, as mentioned in the definition of $T_\phi$ above, we add a curved segment to $T_\phi''$ between the vertex $\xi$ and $\overline{\phi}_i(\xi)$, whenever $\overline{\phi}_i(\xi)$ is defined.

We next consider the structure of the pseudo-group $G^*_K$. The analog results for the pseudogroup generated by $\{\overline{\psi}, \overline{\phi}_1, \overline{\phi}_2\}$ are studied in Section 21. The collection

$$G^{(1)}_K = \{Id, (\psi)^\pm 1, (\phi_1^+)^\pm 1, (\phi_2^+)^\pm 1, (\phi_2^-)^\pm 1, (\phi_2^-)^\pm 1\}$$

is a symmetric generating set for the pseudo-group $G^*_K$. Let $G^{(n)}_K \subset G^*_K$ be the collection of maps defined by the restrictions of compositions of at most $n$ elements of $G^{(1)}_K$. The "word metric" on $G^*_K$ is defined by setting $\|\varphi\| \leq n$ if $\varphi \in G^{(n)}_K$.

Recall that $\mathfrak{M}_0$ is invariant under the flow $\Phi_t$ and so each $x \in \mathfrak{M}_0$ has infinite orbit. Set $\mathfrak{M}_{\mathfrak{R}_a} = \mathfrak{M} \cap \mathfrak{R}_a$. We use the level function defined in Section 10 to show that the words for the restricted action $G^*_K | \mathfrak{M}_{\mathfrak{R}_a}$ have a normal form. First, we define:

**DEFINITION 14.1.** A word in $G^*_K$ is said to be monotone (increasing) if it has the form

$$\varphi = \psi^{i_m} \circ \phi_1^{i_m} \circ \cdots \circ \psi^{i_2} \circ \phi_2^{i_2} \circ \psi^{i_1} \circ \phi_1^{i_1} \circ \psi^{i_0}$$

where each $i_\ell = 1, 2$, each $\ell_k \geq 0$. Let $\mathcal{M}(n)$ be the set of monotone words of length at most $n$, with $\mathcal{M}(0) = \{Id\}$. Then let $\mathcal{M}(\infty)$ be the union of all collections $\mathcal{M}(n)$ for $n \geq 0$.

Observe that for $\varphi \in \mathcal{M}(\infty)$ as in (71), its length satisfies $\|\varphi\| = m + \ell_0 + \ell_1 + \cdots + \ell_m$.

Also, note that the collection of maps $\mathcal{M}(\infty) \subset G^*_K$ forms a monoid, as composition of maps of the form (71) is again of that form, assuming that the composition has non-empty domain.

**REMARK 14.2.** Observe that if the level along the action of a word in $G^*_K$ is monotone increasing, the word is written as a composition of the maps $\phi_1^+, (\phi_1^-)^{-1}$ and $\psi$, for $i = 1, 2$. By Lemma 13.8, the action of $(\phi_i^-)^{-1}$ can be replaced by $\phi^k \circ \phi_i^+ \circ \psi^{-1}$ for some $k > 0$. The word obtained by this substitution is still monotone increasing in level.

Even if the substitution made the expression of an element in $G^*_K$ longer, the counting method below does not consider this nuance and the estimation on the number of monotone words is thus an estimation of words along which the level is monotone increasing.

**PROPOSITION 14.3.** Let $\varphi \in G^*_K$ with $\|\varphi\| \leq n$ and $\text{Dom}(\varphi) \cap \mathfrak{M}_{\mathfrak{R}_a} \neq \emptyset$. Then there exists a factorization $\varphi = \varphi^+ \circ \varphi^-$, where $\varphi^+ \in \mathcal{M}(n')$ and $(\varphi^-)^{-1} \in \mathcal{M}(n'')$ for integers $n', n''$ with $n' + n'' \leq n$. Moreover, we have $\text{Dom}(\varphi) \subset \text{Dom}(\varphi^+ \circ \varphi^-)$. The factorization $\varphi = \varphi^+ \circ \varphi^-$ is said to be the normal form for the word $\varphi$. 
Proof. By hypothesis we have that \( \varphi = \varphi_k \circ \cdots \circ \varphi_1 \) for some \( k \leq n \) and \( \varphi \in \mathcal{G}_K^{(1)} \) for every \( 1 \leq \ell \leq k \). Since \( \mathcal{M} \) is the closure of \( \mathcal{M}_0 \), and we assume that \( \text{Dom}(\varphi) \cap \mathcal{M}_0 \neq \emptyset \), there exists a point \( \xi_0 \in \text{Dom}(\varphi) \cap \mathcal{M}_0 \cap \mathcal{R}_0 \). Set \( \xi_\ell = \varphi_k \circ \cdots \circ \varphi_1(\xi_0) \).

The idea behind the proof is best described in terms of the tree \( T_\varphi \) illustrated in Figure 36. Given \( \xi_0 \in \mathcal{M}_0 \cap \mathcal{R}_0 \) there exist a unique point \( x \in \mathcal{R}' \cap \mathcal{R}_0 \) such that \( \Phi_t(x) = \xi_0 \) for some \( t > 0 \). The \( K \)-orbit segment \([x, \xi_0)_K\) is a path in \( \mathcal{M}_0 \) so can be deformed into a path in the tree \( T_\varphi \) from \( \omega_0 \) to the closest endpoint of the \( \gamma_0 \) or \( \lambda_0 \) curve containing \( \xi_0 \). This tree path define a unique monotone word \( \varphi_{\xi_0} \in \mathcal{G}_K^* \) such that \( \varphi_{\xi_0}(x) = \xi_0 \). Analogously, there exist a unique monotone word \( \varphi_{\xi_k} \in \mathcal{G}_K^* \) and a unique point \( y \in \mathcal{R}' \cap \mathcal{R}_0 \) such that \( \varphi_{\xi_k}(y) = \xi_k \). The expression we are looking for is then the simplified word obtained from \( \varphi_{\xi_k} \circ (\varphi_{\xi_0})^{-1} \), that is a product of a monotone word with the inverse of another monotone word.

Let us start the proof. By Proposition 10.1, the level function \( n_0 : \mathcal{M}_0 \to \mathbb{N} \) is well defined. Let \( n_*(\varphi, \xi_0) = \min\{n_0(\xi_\ell) \mid 0 \leq \ell \leq k\} \) and \( n^*(\varphi, \xi_0) = \max\{n_0(\xi_\ell) \mid 0 \leq \ell \leq k\} \). We consider the following cases:

1. \( n_0(\xi_0) \leq n_0(\xi_k) \) and \( n_0(\xi_0) = n_*(\varphi, \xi_0) \).
2. \( n_0(\xi_0) \leq n_0(\xi_k) \) and \( n_0(\xi_0) > n_*(\varphi, \xi_0) \).
3. \( n_0(\xi_0) > n_0(\xi_k) \) and \( n_0(\xi_k) = n_*(\varphi, \xi_0) \).
4. \( n_0(\xi_0) > n_0(\xi_k) \) and \( n_0(\xi_k) > n_*(\varphi, \xi_0) \).

Consider case (1), for which the plot of the function appears as in Figure 38. Let \( \ell_1 > 0 \) be the least index such that there exists \( \ell_2 > \ell_1 \) with \( n_0(\xi_{\ell_1}) = n_0(\xi_{\ell_2}) \) and \( n_0(\xi_{\ell_1}) > n_0(\xi_{\ell_2}) \) for all \( \ell_1 < \ell < \ell_2 \). By Proposition 5.3 combined with Lemma 13.9, we can replace the subword \( \varphi_{\ell_2} \circ \varphi_{\ell_2-1} \circ \cdots \circ \varphi_{\ell_1} \), by the map \( \psi \), thus changing a non-monotone subword of the expression of \( \varphi \) by \( \psi \). The new word has length less than \( n \) and, since the domain of \( \psi \) contains the domain of the other generators in \( \mathcal{G}_K^{(1)} \), its domain contains the domain of \( \varphi \). Repeating this process a finite number of times we obtain a monotone word \( \varphi^+ \), and putting \( \varphi^{-} = \text{Id} \) we obtain the conclusion of Proposition 14.3.

![Figure 38. Plot of the level function \( n_0(\xi_\ell) \)](image)

The subword substitution operations in the proof of case (1) above have alternate interpretations. In terms of the subgraph of the level function in Figure 38, we are replacing any parts of the graph which are not increasing with a horizontal line, which corresponds to substituting in some power of the generator \( \psi^n \) for the subword. In terms of the tree \( T_\varphi \) in Figure 36, we are following a path that takes a short-cut across the base of each propeller, so that the resulting path follows a curve whose distance from the root is monotonically increasing.

For case (2), let \( \ell_* \) be the first index for which \( n_0(\xi_{\ell_*}) = n_*(\varphi, \xi_0) \). We can apply the method of the first case from \( \xi_0 \) to \( \xi_{\ell_*} \), to change \( \varphi \) for a word of the form \( \varphi_k \circ \cdots \circ \varphi_{\ell_*+1} \circ \varphi_{\ell_*+1} \) satisfies the hypothesis of the first case and hence can be expressed as a monotone word. This concludes the second case.

In terms of the tree \( T_\varphi \), the point \( \xi_{\ell_*} \) corresponds to a vertex point in the tree which is the closest to the root vertex in the path in \( \mathcal{M}_0 \) between \( \xi_0 \) and \( \xi_k \).

We are left with the cases where \( n_0(\xi_0) > n_0(\xi_k) \). In case (3), let \( \ell_* \leq k \) be the first index for which \( n_0(\xi_{\ell_*}) = n_*(\varphi, \xi_0) \). As in case (2), we can change the expression of \( \varphi \) for \( \varphi_k \circ \cdots \circ \varphi_{\ell_*+1} \circ \varphi_{\ell_*} \) with \( (\varphi_*)^{-1} \).
monotone. Since \( n_\ell(\varphi, \xi_0) = n_0(\xi_k) \), Proposition 5.5 implies that the word \( \varphi_k \circ \cdots \circ \varphi_{\ell+1} \) can be replaced by a certain number of consecutive \( \psi \)-maps, the number being less or equal to \( k - \ell \). Thus \( \varphi \) can be expressed as the inverse of a monotone word and the conclusion follows.

The proof for case (4) is analogous to that of case (2). \( \square \)

We next develop an estimate for the cardinality of the set \( \mathcal{M}(n) \) as a function of \( n \). This will be used in later sections when we consider various entropy invariants of the flow \( \Phi \).

For \( \varphi \in \mathcal{M}(n) \) with \( \| \varphi \| = n \), assume that \( \varphi \) has the normal form (71). Let \( \xi_0 \in \mathcal{M}_0 \cap \text{Dom}(\varphi) \), then let \( \xi_\ell \) for \( 0 < \ell \leq n \) denote the images of \( \xi_0 \) under the partial products of the factors in (71). Note that \( r(\xi_{\ell+1}) \geq r(\xi_\ell) \), with equality if \( \xi_{\ell+1} = \psi(\xi_\ell) \), and with strict inequality if \( \xi_{\ell+1} = \phi_j^+(\xi_\ell) \) and \( \xi_\ell \neq \omega_j \) for \( j = 1, 2 \).

Observe that in the case where \( \xi_{\ell+1} = \phi_j^+(\xi_\ell) \), the point \( \xi_\ell \) must lie in the domain of \( \phi_j^+ \). Since \( r(\xi_\ell) \geq 2 \), if \( j = 2 \) and \( \xi_\ell = \psi^i(\xi_{\ell-i}) \), then \( i > 0 \) must be sufficiently large so that the orbit transverses bottom half of the rectangle \( \mathcal{R}_0 \) in order to enter the domain of \( \phi_2^+ \). By definition (37), the integer \( \Delta(r) = |\Theta(r)/2\pi| \) is the number of intersections for the Wilson flow to reach the line \( \{ z = 0 \} \cap \mathcal{R}_0 \), where \( \Delta(r) \to \infty \) as \( r \to 2 \). Thus, \( i > \Delta(r) \) where \( r = r(\xi_{\ell-i}) \).

**Lemma 14.4.** For each \( b \geq 1 \), there exists integers \( N_b > 0 \) and \( L_b > 0 \) such that for \( \varphi \in \mathcal{M}(n) \) of the normal form (71) with \( \ell_0 = 0 \), \( \ell_1 \leq b \) and sub-index \( m \) equaling the number of insertion maps in \( \varphi \), then \( m \leq N_b \) and each \( \ell_k \leq L_b \) for \( 1 \leq k \leq b \). Moreover, \( N_b \to \infty \) as \( b \to \infty \).

**Proof.** The assumption that no factor in (71) is a map \( \psi \) implies that the action of \( \varphi \) on \( \mathcal{R}_0 \) can be described in terms of the action of the generators \( \{ \psi, \phi_1^+, \phi_2^+ \} \) on the families of nested ellipses in \( \mathcal{R}_0 \) given by the intersection of \( \mathcal{M}_0 \cap \mathcal{R}_0 \). This is described in Lemmas 13.5, 13.6, 13.7 and 13.9. The assumption \( \ell_0 = 0 \) implies \( \varphi \) begins with the action of \( \phi_1^+ \) and thus the special point \( \omega_1 \in \text{Dom}(\varphi) \).

Recall that the function \( N(r) \) for \( r > 2 \) was defined in Lemma 6.1 and is the maximum increase in the level function along the orbit of \( K \) starting at an entry point \( \xi \) with \( r(\xi) = r \). As shown in Section 6 the function \( N(r) \to \infty \) as \( r \to 2 \). We are given \( b \geq 1 \), so set

\[
(72) \quad \rho_b = \min \{ r(\phi_1^+ \circ \psi^{\ell_1} \circ \phi_1^+(\xi)) \mid \xi \in \text{Dom}(\varphi) \text{ and } 0 \leq \ell_1 \leq b \} > 2.
\]

Then \( N(\rho_b) \) is the maximal increase in the level function starting from the point \( \phi_1^+ \circ \psi^{\ell_1} \circ \phi_1^+(\xi) \), and thus \( m \leq N(\rho_b) + 2 \). Set \( N_b = N(\rho_b) + 2 \). Note that \( N_b \to \infty \) as \( b \to \infty \).

Let \( T_b > 0 \) be such that for all \( x \in \partial \mathcal{R}_b \mathcal{W} \) with \( \rho_b \leq r(x) \leq 3 \), then the Wilson flow \( \Psi_t(x) \) exits \( \partial \mathcal{R}_b \mathcal{W} \) with \( t \leq T_b \). Then \( L_b \) can be taken to be the greatest integer less than \( T_b/4\pi \). \( \square \)

We use Lemma 14.4 to obtain an estimate on the growth of the function \( \#\mathcal{M}(n) \).

**Proposition 14.5.** For each \( b \geq 1 \), there is a polynomial function \( P_b(n) \) of \( n \) such that the cardinality of the set \( \mathcal{M}(n) \) satisfies

\[
(73) \quad \#\mathcal{M}(n) \leq P_b(n) \cdot 2^{(n/b)}.
\]

**Proof.** For \( \varphi \in \mathcal{M}(n) \) with \( \| \varphi \| = n \), assume that \( \varphi \) has the normal form (71).

For the given value of \( b \), let \( i(\varphi, b) \geq 1 \) be the index such that \( \ell_i \geq b \) for all \( 1 \leq i < i(\varphi, b) \), and \( \ell_i < b \) for \( i = i(\varphi, b) \). Factor \( \varphi = \varphi^{(b)} \cdot \varphi^{(b+1)} \) where \( \varphi^{(b)} \) starts with the map \( \phi_1^+_{i(\varphi, b)} \) and \( \varphi^{(b+1)} \) starts with the map \( \psi^{\ell_0} \).

Let \( k(\varphi, b) \) denote the number of factors in \( \varphi^{(b)} \) of the form \( \phi_1^+ \). By Lemma 14.4, \( 0 \leq k(\varphi, b) \leq N_b \). We have \( \| \varphi^{(b)} \| \leq n \), so the indices of the factors of the form \( \phi_1^+ \) appearing in \( \varphi^{(b)} \) gives a choice of \( k(\varphi, b) \) indices out of the maximum of \( n \) possibilities, and for each choice of index, let \( i = 1, 2 \). Thus, the number of such
words has an upper bound \( \binom{n}{k} \cdot 2^k \) for \( k = k(\varphi, b) \). Then set

\[
B'(n, b) = \left( \binom{n}{0} \cdot 2^0 + \binom{n}{1} \cdot 2^1 + \cdots + \binom{n}{N_b} \cdot 2^{N_b} \right)
\]

Observe that \( B'(n, b) \) is a polynomial function of \( n \) of degree at most \( N_b \). It follows that \( B'(n, b) \) is an upper bound on the number of possible words \( \varphi^{(b)} \) which can arise for \( \varphi \in \mathcal{M}(n) \) and the given value of \( b \).

Next, consider the number of possible choices for the words \( \varphi^{(b)} \) which can arise. For \( p = i(\varphi, b) - 1 \), we then can write

\[
\varphi^{(b)} = \psi_t \circ \phi_{i_p}^+ \circ \psi_{t_{p-1}} \circ \cdots \circ \psi_t \circ \phi_{i_1}^+ \circ \psi_{t_0}
\]

where each index \( \ell_i > b \) for \( 1 \leq i \leq p \), and so \( p \leq n/(b + 1) < n/b \). Observe that for \( 1 \leq k \leq p \), there are at most \( 2^p \) possible choices of \( i_k \), so the number of such choices is bounded above by \( 2^{n/b} \).

The placement of the terms \( \phi_{i_k}^+ \), or equally the choices of the values \( \ell_i \geq b \), is given by a more complicated choice function. Observe that \( b \leq \ell_0 \leq n \), and \( b \leq \ell_1 \leq n - \ell_0 - 1 \leq n - b - 1 \). Thus, there are at most \( n - 2b \) possible values for \( \ell_1 \). Next, we have \( b \leq \ell_2 \leq n - \ell_0 - \ell_1 - 1 \leq n - 2b - 2 \), so that there are at most \( n - 3b - 1 \) possible values for \( \ell_2 \). We continue in this way up to the choice of \( \ell_p \). The number of possible choices of the indices \( (\ell_0, \ell_1, \ldots, \ell_p) \) is then bounded above by the products of the maximal number of values for each \( \ell_i \) for \( 0 \leq i \leq p \), so is a polynomial in \( n \) of degree at most \( p + 1 \), which we denote by \( B''(n, b) \). Set

\[
P_b(n) = B'(n, b) \cdot B''(n, b)
\]

The estimate (73) follows.

\[\square\]

**COROLLARY 14.6.** The function \( n \mapsto \# \mathcal{M}(n) \) has subexponential growth. That is, we have

\[
\lim_{n \to \infty} \frac{\ln(\# \mathcal{M}(n))}{n} = 0.
\]

**Proof.** For each \( b \geq 1 \), the estimate (73) implies that the limit in (77) is bounded above by \( \ln(2)/b \) hence equals 0. \[\square\]

## 15. INTERNAL NOTCHES AND BUBBLES

In this section, we analyze the properties of the “bubbles” that arise when the interior of a propeller intersects an insertion region, resulting in an internal notch, as discussed in Section 12 and illustrated in Figure 25. Recall that an internal notch in a propeller \( P_\gamma \) is a rectangular hole whose boundary is disjoint from the boundary of \( P_\gamma \). The \( \Psi_t \)-flow of an internal notch generates a compact surface, as defined by (53) and called a “bubble”. A key result of this section is that the bubbles obtained from internal notches all admit a uniform bound on their complexity: the difference of level between any two points in a bubble is uniformly bounded. This is shown in Proposition 15.4.

Assume that the construction of the plug \( \mathcal{K} \) and the flow \( \mathcal{K} \) satisfies Hypotheses 12.1 and 12.2.

In Sections 12 and 13, the orbits of the special points \( p^+_1 \) and \( p^+_2 \) were used to label the boundary notches of the propellers \( P'_\gamma \), \( P'_\lambda \), \( P''_\lambda \) and \( P'_{\lambda'} \), which are bounded by \( \mathcal{W} \)-arcs spaced along the edges of the propellers. A propeller formed from any of these four families and at any level \( n \geq 1 \), might also have internal notches as described in Section 12. In this section, we give an analogous labeling for the internal notches and bubbles of the propellers \( P'_\gamma \) and \( P'_{\lambda'} \), which then also applies to the double propellers \( P'_\gamma \) and \( P'_{\lambda'} \).

First, recall the data that is given. The curve \( \gamma' = R \cap L_{-1}^- \) denotes the intersection of the face \( L_{-1}^- \) with the Reeb cylinder \( R \), as in (45) and \( \gamma' = R \cap L_{-1}^+ \) is its facing curve. Define \( \gamma = \sigma_{-1}(\gamma') \subset L_{-1}^- \subset \partial_{-1}^- \mathcal{W} \) with facing curve \( \gamma = \sigma_{-1}(\gamma') \subset L_{-1}^- \subset \partial_{-1}^+ \mathcal{W} \). The curve \( \kappa' \subset L_{-1}^- \) is the intersection of the \( \Psi_t \)-flow of the interval \( J_0 \) with \( L_{-1}^- \) and \( \kappa = \sigma_{-1}(\kappa') \subset L_{-1}^- \), as illustrated in Figure 26.
The curve $\lambda' = \mathcal{R} \cap \mathcal{L}_{2}^{+}$, denotes the intersection of the face $\mathcal{L}_{2}^{-}$ with the Reeb cylinder $\mathcal{R}$, as in $[45]$ and $\mathcal{X}' = \mathcal{R} \cap \mathcal{L}_{2}^{+}$ is its facing curve. Define $\lambda = \sigma_{2}^{-1}(\lambda') \subset \partial_{\mathcal{N}}^\mathcal{W}$ with facing curve $\mathcal{X} = \sigma_{2}^{-1}(\mathcal{X}') \subset \partial_{\mathcal{X}}^\mathcal{W}$. The curve $\lambda' \subset \mathcal{L}_{2}^{-}$ is the intersection of the $\Psi_{t}$-flow of the interval $K_{0}$ with $\mathcal{L}_{2}^{-}$ and $\lambda = \sigma_{1}^{-1}(\lambda') \subset \mathcal{L}_{2}^{+}$, again as illustrated in Figure 29.

Consider first the propeller $P_{\gamma} \subset \mathcal{W}$ generated by the $\Psi_{t}$-flow of $\gamma$, and let $P'_{\gamma} = P_{\gamma} \cap \mathcal{W}'$ be the notched propeller. The intersection of $P'_{\gamma}$ with $\mathcal{R}_{0}$ consists of an infinite family of arcs with lower endpoints in the vertical line segment $J_{0}$ that accumulate on $\omega_{1}$ and upper endpoints that accumulate on $\omega_{2}$, as in Figure 20. This implies, as observed in Section 12, that $P'_{\gamma}$ has an infinite number of (boundary) notches and a finite number $|b| \geq 0$ of internal notches. We assume for the rest of this section that $b < 0$ and investigate the properties of the bubbles which result from their $\Psi_{t}$-flows.

Let $\gamma'(i, \ell) \subset \mathcal{L}_{i}^{-}$ for $b \leq \ell < 0$ denote the intersection of the boundaries of the internal notches of $P'_{\gamma}$ with $\mathcal{L}_{i}^{-}$. Observe that both endpoints of such a curve are contained in the boundary $\partial \mathcal{L}_{i}^{-}$, as for the curve $\gamma'(1, -1)$ in Figure 26 and the the curve $\gamma'(2, -1)$ in Figure 27. The $\Psi_{t}$-flow of each $\gamma'(i, \ell)$, from $\mathcal{L}_{i}^{-}$ to $\mathcal{L}_{i}^{+}$, defines a rectangular region in the interior of $P_{\gamma}$.

Set $\gamma(i, \ell) = \sigma_{1}^{-1}(\gamma'(i, \ell)) \subset \mathcal{L}_{i}^{-}$ and parametrize $\gamma(i, \ell)$ by $\gamma(i, \ell) : [0, 2] \to \mathcal{L}_{i}^{-}$ in such a way that:

- $2 < r(\gamma(i, \ell)(1)) \leq r(\gamma(i, \ell)(s))$ for every $s \in [0, 2]$;
- $r(\gamma(i, \ell)(0)) = r(\gamma(i, \ell)(2)) = 3$, so both endpoints lie in the boundary $\partial_{\mathcal{X}}^\mathcal{W} \cap \partial_{\mathcal{R}}^\mathcal{W}$.

Analogously define $\lambda(i, \ell) \subset \mathcal{L}_{i}^{-}$ for $b \leq \ell < 0$. Since the $\gamma$ and $\lambda$ curves are interlaced the number of internal notches in $P'_{\gamma}$ is equal to $\pm 1$ the number of internal notches in $P'_{\lambda}$. To simplify the notation, we assume that there is the same number of internal notches in $P'_{\lambda}$ and $P'_{\gamma}$.

**Proposition 15.1.** There exists $r_{b} > 2$ such that for any $b \leq \ell < 0$ and $i = 1, 2$, then $r(x') \geq r_{b}$ for all $x' \in \gamma(i, \ell)$ and all $x' \in \lambda(i, \ell)$.

**Proof.** For a curve $\zeta : [0, 1] \to \mathcal{W}$, set $r(\zeta) = \min \{r(\zeta(s)) \mid 0 \leq s \leq 1\}$. Then set

$$ r_{b} = \min \{r(\kappa(1, 0)), r(\kappa(2, 0)), r(\chi(1, 0)), r(\chi(2, 0))\} > 2. $$(78)

Consider first the case $\gamma(1, \ell)$ for $b \leq \ell < 0$. Recall that $p(1; 1, 0) \in \kappa$ is the endpoint of the curve $\gamma(1, 0) \subset \mathcal{L}_{1}^{-}$ and satisfies $r(p(1; 1, 0)) > 2$. Define a curve $Y(\kappa, 1) \subset \mathcal{L}_{1}^{-}$ with endpoints in $\{r = 3\}$ which first follows the path $\kappa(1, 0)$ from its endpoint in $\{r = 3\}$ to its endpoint $p(1; 1, 0)$, then follows the curve $\kappa$ back to its boundary point in $\{r = 3\}$. This is illustrated in Figure 39. Note that $Y(\kappa, 1)$ divides $\mathcal{L}_{1}^{-}$ into two topological discs and consider the closure $D(\kappa, 1)$ of the disk contained in the region $r > 2$. The radius function restricted to $D(\kappa, 1)$ has a minimum value greater or equal to $r_{b}$.

Note that for $b \leq \ell < 0$, we have $\gamma(1, \ell) \subset D(\kappa, 1)$ and hence $r(\gamma(1, \ell)) \geq r_{b}$.

The radius estimate for the cases $\gamma(2, \ell)$, $\lambda(1, \ell)$ and $\lambda(2, \ell)$ follow in the similar manner, using the corresponding curves $Y(n, 2)$, $Y(\chi, 1)$ or $Y(\chi, 2)$. □

In what follows, we restrict our attention to the surfaces derived from the $\Psi_{t}$-flow of the curves $\gamma(1, \ell)$ for $b \leq \ell < 0$, which form the “bubbles” in the propeller $P_{\gamma}$. An analogous discussion applies to the curves $\gamma(2, \ell)$, $\lambda(1, \ell)$ and $\lambda(2, \ell)$.

The endpoints of $\gamma(1, \ell_{1})$ are contained in $\partial_{\mathcal{R}}^\mathcal{W}$ and thus their $\mathcal{W}$-orbits escape through $\partial_{\mathcal{X}}^\mathcal{W}$ without intersecting $\mathcal{R}_{0}$. Thus, the intersection $P_{\gamma(1, \ell_{1})} \cap \mathcal{R}_{0}$ is a finite family of circles contained in the region $r \geq r(\gamma(1, \ell_{1})(1)) > r_{b}$. The number of circles is bounded by $\Delta(r(\gamma(1, \ell_{1})(1)) + 1$, where $\Delta$ is defined by (37). The number of circles thus admits the uniform upper bound $\Delta(r_{b}) + 1$.

Since $\gamma(1, \ell_{1})$ is contained in the region of $\mathcal{L}_{1}^{-}$ bounded by the curve $Y(\kappa, 1)$ introduced in the proof of Proposition 15.1, this is in the region of $\mathcal{L}_{1}^{-}$ bounded by $\Gamma$. The circles formed by the intersection $P_{\gamma(1, \ell_{1})} \cap \mathcal{R}_{0}$ lie in the discs bounded by a certain $\Gamma_{0}(\ell_{2})$, for $\ell_{2} \geq a$. Assuming that $P_{\gamma(1, \ell_{1})} \cap \mathcal{R}_{0}$ is non-empty, the first curve in the intersection is in the region of $\mathcal{R}_{0}$ bounded by $\Gamma_{0}(a)$, with $a$ as in Remark 13.2 and the following
curves are obtained by applying the Wilson map \( \psi \in \mathcal{G}_K \). Thus if the intersection is formed by \( n \) curves, the first one is in the region bounded by \( \Gamma_0(a) \), the second one in the region bounded by \( \Gamma_0(a + 1) \) and the \( k \)th curve is in the region bounded by \( \Gamma_0(a + k) \), for \( 0 \leq k \leq n \).

We extend the labeling to \( P_{a, \ell_1, \ell_2} \cap \mathbb{R}_0 \) by naming the curves in the intersection \( \gamma_0(1, \ell_1; \ell_2) \), for \( a \leq \ell_2 \leq a + n \), in such a way that \( \gamma_0(1, \ell_1; \ell_2) \) is contained in the disc bounded by \( \Gamma_0(\ell_2) \). Observe that \( \ell_1 \) is negative and that the connected component of \( P_{a, \ell_1, \ell_2} \cap \mathbb{R}_0 \) closer to the boundary \( r = 3 \) of \( \mathbb{R}_0 \) is denoted by \( \gamma_0(1, \ell_1; a) \). This convention agrees with the labeling system introduced in the previous sections. Analogously we have:

- The curves in the intersection \( P_{a, \ell_1, \ell_2} \cap \mathbb{R}_0 \) are labeled \( \lambda_0(1, \ell_1; \ell_2) \) and are contained in regions bounded by \( \Gamma_0 \) curves. Thus \( \lambda_0(1, \ell_1; \ell_2) \) lies inside the region bounded by \( \Gamma_0(\ell_2) \).
- The curves in the intersection \( P_{\gamma(1, \ell_1, \ell_2)} \cap \mathbb{R}_0 \) are labeled \( \gamma_0(2, \ell_1; \ell_2) \) and are contained in regions bounded by \( \lambda_0 \) curves. Thus \( \gamma_0(2, \ell_1; \ell_2) \) lies inside the region bounded by \( \lambda_0(\ell_2) \).
- The curves in the intersection \( P_{\lambda(1, \ell_1, \ell_2)} \cap \mathbb{R}_0 \) are labeled \( \lambda_0(2, \ell_1; \ell_2) \) and are contained in regions bounded by \( \lambda_0 \) curves. Thus \( \lambda_0(2, \ell_1; \ell_2) \) lies inside the region bounded by \( \lambda_0(\ell_2) \).

For the notched propellers \( P'_{\gamma(i, \ell_1)} \) and \( P'_{\lambda(i, \ell_1)} \), for \( i = 1, 2 \) and \( b \leq \ell_1 < 0 \), obtained by intersecting the corresponding propeller with \( \mathbb{W} \), their images \( \tau(P'_{\gamma(i, \ell_1)}) \) and \( \tau(P'_{\lambda(i, \ell_1)}) \) form part of \( \mathfrak{M}_0 \).

We now describe the compact surfaces \( S_{(1, \ell_1)} \subset \mathbb{K} \) for \( b \leq \ell_1 < 0 \) introduced in (53). Consider the notched propellers \( P_{\gamma(1, \ell_1)} \cap \mathbb{W} \) for \( b \leq \ell_1 < 0 \). If \( P_{\gamma(1, \ell_1)} \cap \mathbb{W} \) is non-empty, let \( \gamma'(1, \ell_1; 1, \ell_2) \) be the curves in the intersection. Observe that \( \ell_2 \) admits finitely many possible values, at most \( \Delta(r_0) + 1 < \infty \). In the same way if \( P_{\gamma(1, \ell_1)} \cap \mathbb{L}_2^{-} \) is non-empty, let \( \gamma'(1, \ell_1; 2, \ell_2) \) be the curves in the intersection. Observe that \( \ell_2 \) admits finitely many possible values, at most \( \Delta(r_0) + 1 < \infty \). Since \( \gamma_0(1, \ell_1; 1, b - 1) \subset \mathbb{R}_0 \) is the region bounded by \( \Gamma_0(b - 1) = \gamma_0(b - 1) \cup \kappa_0(b - 1) \), the \( K \)-orbits of points in \( \gamma_0(1, \ell_1; b - 1) \) come back to \( \mathbb{R}_0 \) before hitting the insertions. Hence the first curve in \( P_{\gamma(1, \ell_1)} \cap \mathbb{L}_2^{-} \) is either \( \gamma(1, \ell_1; 1, b) \) or \( \gamma(1, \ell_1; 1, b + 1) \).

Consider now the curves \( \gamma(1, \ell_1; 1, \ell_2) = \sigma_1^{-1}(\gamma'(1, \ell_1; 1, \ell_2)) \in L_1^- \) with \( b \leq \ell_1 < 0 \) and \( b \leq \ell_2 \). Two possible situations arise, as illustrated in Figure 40:

- \( \gamma'(1, \ell_1; 1, \ell_2) \) contains a point of the \( \mathbb{W} \)-orbit of \( \gamma(1, \ell_1; 1) \). In this case the curve is an arc with endpoints in \( \partial L_1^- \). Thus \( \gamma(1, \ell_1; 1, \ell_2) \) generates a finite double propeller \( P_{\gamma(1, \ell_1; 1, \ell_2)} \subset \mathbb{W} \). The Radius Inequality implies that the minimum radius along \( \gamma(1, \ell_1; 1, \ell_2) \) is strictly bigger than \( r(\gamma(1, \ell_1; 1)) > r_b \),

![Figure 39. The curve \( \Upsilon(\gamma, 1) \) and the disc \( D(\kappa, 1) \) in \( L_1^- \)](image)
and thus the number of circles in \( P_{\gamma(1,\ell_1;1,\ell_2)} \cap R_0 \) is less or equal that the number of circles in the intersection \( P_{\gamma(1,\ell_1)} \cap R_0 \).

- \( \gamma'(1,\ell_1;1,\ell_2) \) does not contains points in the \( W \)-orbit of \( \gamma(1,\ell_1;1,\ell_2) \) and thus it is formed by the union of two connected components, each being an arc with endpoints in \( \partial L^- \). In this case we obtain from \( \gamma(1,\ell_1;1,\ell_2) \) two double finite propellers whose union we denote by \( P_{\gamma(1,\ell_1;1,\ell_2)} \subset W \). Observe that the Radius Inequality implies that the minimum radius along any component of \( \gamma(1,\ell_1;1,\ell_2) \) is strictly bigger than \( r(\gamma(1,\ell_1;1,\ell_2)) > r_b \), and thus the number of circles in \( P_{\gamma(1,\ell_1;1,\ell_2)} \cap R_0 \) is less or equal that twice the number of circles in the intersection \( P_{\gamma(1,\ell_1)} \cap R_0 \).

The construction terminates if \( P_{\gamma(1,\ell_1;1,\ell_2)} \cap L^-_i = \emptyset \) for \( i = 1, 2 \); otherwise, it continues in a recursive manner.

**Figure 40.** Possible intersections of \( P_{\gamma(1,\ell_1)} \) with \( L^-_i \) for \( b \leq \ell_1 < 0 \)

We comment on the details of Figure 40. There are two \( \Gamma' \) curves, with the corresponding \( \kappa' \) in dotted lines, and one \( \Lambda' \) curve, with the corresponding \( \chi' \) in dotted lines. These are level 1 curves. At level two, two curves in the intersection \( P_{\gamma(1,\ell_1)} \cap L^-_i \) are illustrated: \( \gamma'(1,\ell_1;1,0) \) with one connected component, and \( \gamma'(1,\ell_1;1,-1) \) formed of the union of two connected components. These curves are contained in the regions of \( L^-_i \) bounded by \( \Gamma'(1,0) \) and \( \Gamma'(1,-1) \), respectively.

Analogous considerations apply to the curves \( \gamma(1,\ell_1;2,\ell_2) \) thus we obtain two families of level 3 propellers \( P_{\gamma(1,\ell_1;i_2,\ell_2)} \) for \( i_2 = 1, 2 \) and \( b \leq \ell_1 < 0 \) that are part of \( S_{\gamma(1,\ell_1)} \). Let \( P'_{\gamma(1,\ell_1;i_2,\ell_2)} = P_{\gamma(1,\ell_1;i_2,\ell_2)} \cap W' \). Observe that \( \tau(P'_{\gamma(1,\ell_1;i_2,\ell_2)}) \subset S_{\gamma(1,\ell_1)} \). Thus for \( b \leq \ell_1 < 0 \),

\[
\bigcup_{i_2=1,2} \bigcup_{\ell_2} \tau(P'_{\gamma(1,\ell_1;i_2,\ell_2)}) \subset S_{\gamma(1,\ell_1)},
\]

where the union is taken over all the possible values of \( \ell_2 \), once \( i_2 \) is given.
LEMMA 15.2. There exists $N > 0$ such that for any $x \in S_γ(1, \ell_1)$ with $x \notin \overline{γ(1, \ell_1)}$, then $2 \leq n_0(x) \leq N + 1$.

Proof. The boundary of $S_γ(1, \ell_1)$ is composed by $τ(γ(1, \ell_1)) \subset E_1$, the facing curve $τ(\overline{γ(1, \ell_1)}) \subset S_1$ and the two $K$-orbit segments going from the endpoints of the entry curve to the endpoints of the facing exit curve. Since $r(γ(1, \ell_1)) = 2$ and $γ(1, \ell_1)$ is a level 2 curve, then for any $x \in S_γ(1, \ell_1)$ we know that $n_0(x) \geq 2$.

Consider now $γ(1,0)$. Since $r(γ(1,0)) > r_0 > 2$, the $K$-orbit of every point in $τ(γ(1,0))$ passes through the facing point, and thus attains a maximum level $N + 1$. Thus $n_0(x) \leq N + 1$.

This implies that the construction process above terminates after at most $N$ steps. Thus $S_γ(1, \ell_1)$ is the union of

\[ \bigcup_{1 \leq n \leq N+1} τ(P'_γ(1, \ell_1;i_2, \ell_2;\ldots;i_n, \ell_n)) \]

for any combinations of indices, $(i_2, \ell_2;\ldots;i_n, \ell_n)$, where $b \leq \ell_i < 0$.

In a similar way we obtain the compact surfaces $S_γ(2, \ell), S_{λ(1, \ell)}$ and $S_{λ(2, \ell)}$. We call these surfaces the level 2 bubbles in $M_0$, since they are associated to a level 2 curve.

Recall that in [12] the set $M_0^b$ was described for any value of $b$. The construction of $M_0^b+1$ from $M_0^b$, for $n \geq 1$, follows the lines of the construction of $M_1^b$ from $M_0^b = τ(R')$. To obtain $M_2^b$ we have to add the level 2 points in the $K$-orbits of $γ(1, \ell)$ and $λ(i, \ell)$ for $i = 1, 2$ and $b \leq \ell$ and unbounded. The case $ℓ = 0$ was described in Section [12] here we consider the case $b \leq ℓ < 0$ and $i = 1, 2$, thus the level 2 points in the bubbles $S_γ(i, \ell), S_{λ(i, \ell)}$. If $b \neq 0$, we add to the set $M_0^b$ described in Section [12] the notched propellers $τ(P'_γ(i, \ell_i))$ and $τ(P'_λ(i, \ell_i))$ for $i = 1, 2$ and $b \leq ℓ_i < 0$ and the finite collection of exit curves $τ(γ(i_1, \ell_1;i_2, \ell_2))$ and $τ(λ(i_1, \ell_1;i_2, \ell_2))$.

REMARK 15.3. The propeller $P_γ(i_1, \ell_1)$ with $ℓ_1 \geq 0$ might also have internal notches, that is the intersection $P_γ(i_1, \ell_1) \cap L_{i_2}^-$, for $i_2 = 1, 2$, might have curves that are arcs having both endpoints in $∂L_{i_2}^-$. In this case we denote these curves by $γ(i_1, \ell_1;i_2, \ell_2)$ with $ℓ_2 < 0$ and $ℓ_1 \geq 0$. Again, such a curve generates a level 3 bubble $S_γ(i_1, \ell_1;i_2, \ell_2)$ that is part of $M_0$.

In general a propeller $P_γ(i_1, \ell_1;\ldots;i_n, \ell_n)$ forms part of a bubble if at least one of the indices is negative. Assuming that $ℓ_k$ is the first negative index, then $P_γ(i_1, \ell_1;\ldots;i_n, \ell_n) \subset S_γ(i_1, \ell_1;\ldots;i_n, \ell_n)$, that is a level $k+1$ bubble.

The following result generalizes the above discussion to higher level bubbles.

PROPOSITION 15.4. Let $γ'(i_1, \ell_1;\cdots;i_n, \ell_n) \subset L_{i_0}^-$ be any curve in the construction of $M_0$ with at least one negative index. Let $ℓ_k < 0$ be the first negative index. Then

1. $γ'(i_1, \ell_1;\cdots;i_n, \ell_n) = δ_γ(γ'(i_1, \ell_1;\cdots;i_n, \ell_n))$ generates a finite double propeller or a pair of finite double propellers. Each propeller intersects $R_0$ along at most $K$ closed curves, for a fixed number $K$;

2. for every $x \in S_γ(i_1, \ell_1;\cdots;i_n, \ell_n)$ we have that $n + 1 \leq n_0(x) \leq N + n$, for $N$ as in Lemma [15.2].

Proof. For the first conclusion, observe that $γ(i_1, \ell_1;\cdots;1, \ell_n)$ lies in the region $D(κ, 1) \cup D(χ, 1) \subset L_1^-$ described in the proof of Proposition [15.1] and $γ(i_1, \ell_1;\cdots;2, \ell_n)$ lies in the analogous region $D(κ, 2) \cup D(χ, 2) \subset L_2^-$. Thus the number of circles in the intersection of $P_γ(i_1, \ell_1;\cdots;i_n, \ell_n)$ with $R_0$ is uniformly bounded by $Δ(ℓ_k)+1$.

The second conclusion follows from the arguments above and the proof of Lemma [15.2].

Observe that if $b \neq 0$ the double propellers $P_F$ and $P_A$ will also have internal notches, that is notches that are not intersecting the orbits of $ω_1$ or $ω_2$, accordingly. Thus they will generate bubbles in the same manner as the simple propellers $P_F$ and $P_A$ did.

We consider the case of $P_F$ in some detail. The intersection $P_F \cap L_1^-$ consists of the curves $Γ(1, \ell_1)$ for $b \leq ℓ_1$ and unbounded. For $b \leq ℓ_1 < 0$ the curve $Γ(1, \ell_1)$ consists of two connected components each having its two endpoints in $∂L_1^-$, one that corresponds to $γ(1, \ell_1)$ and the other one $κ(1, \ell_1)$ that belongs to $P_κ \cap L_1^-$. Thus $Γ(1, \ell_1)$ is the disjoint union of $γ(1, \ell_1)$ and $κ(1, \ell_1)$, when $b \leq ℓ_1 < 0$. The curves $γ(1, \ell_1)$ generate
Figure 41. Flattened part of $\mathfrak{M}_0$ with bubbles

the bubbles $S_\gamma(1, \ell_1)$ that form part of $\hat{\mathfrak{M}}_0$ as defined in \([62]\). Analogously, the curves $\kappa(1, \ell_1)$ generate the bubbles $S_\kappa(1, \ell_1)$ that form part of $\hat{\mathfrak{M}}_0$. The results above apply without any changes to the bubbles $S_\kappa(1, \ell_1)$. Let $S_\Gamma(1, \ell_1) = S_\gamma(1, \ell_1) \cup S_\kappa(1, \ell_1) \subset \hat{\mathfrak{M}}_0$.

16. Wandering points and propellers

The open set of wandering points $\mathfrak{W} \subset \mathfrak{M}$ for the flow $\Phi_t$ was defined by \((24)\) in Section \(8\) as a union of the four classes:

$$
\mathfrak{W} = \mathfrak{W}^0 \cup \mathfrak{W}^+ \cup \mathfrak{W}^- \cup \mathfrak{W}^\infty
$$

where $\mathfrak{W}^0$ consist of all finite orbits, $\mathfrak{W}^+$ is contained in the set of forward trapped orbits, $\mathfrak{W}^-$ is contained in the set of backward trapped orbits, and $\mathfrak{W}^\infty$ is contained in the infinite orbits.

For example, $\mathfrak{W}$ contains the orbits of all points in the region $\{r < 2\}$ by Proposition \(8.7\). The orbits of points in $\mathfrak{W}^\infty$ exhibit the most subtle dynamical properties of the four classes. Here is the main result of the section:

**Theorem 16.1.** Let $x \notin \mathfrak{M}$, then $x \in \mathfrak{W}$.

The proof of this result requires the introduction of new classes of double propellers which are used to describe the orbits of points $x \in \mathfrak{R}_0$ which satisfy $r(x) \geq 2$. Recall that a key point in the proofs of Propositions \(7.5\) and \(7.6\) was to analyze the orbits which intersect an entry region $E_i$ in the sets $\tau(\mathcal{E}_i^{+, -})$, as illustrated in Figure \(14\) which consist of points that are mapped from the region $\{r > 2\}$ to the region $\{r < 2\}$ by the insertion maps $\sigma_i$. The corresponding regions $\sigma_i^{-1}(\mathcal{E}_i^{+, -}) \subset \mathcal{L}_i^-$ for $i = 1, 2$ are bounded by what we call “$G - L$” curves. We construct the propellers generated by these curves and consider their intersections with the rectangle $\mathfrak{R}_0$, generating families of “$G_0 - L_0$” curves. These curves divide the region $\mathfrak{R}_0 \cap \{r \geq 2\}$ according to their dynamical behavior, and the regions thus defined are used to encode the trapped wandering
orbits for $\Phi_t$. One important application of this method is Proposition 16.10, which implies that there are no trapped wandering orbits which are strictly contained in the region $\{r > 2\}$.

We introduce the curves $G \subset L_1^-$ and $L \subset L_2^-$, starting with the curve $G$. Recall from Section 3 that the boundary of $L_1^-$ is composed of two arcs, $\alpha_1$ and $\alpha_1'$, as illustrated in Figure 5 with $\alpha_1$ contained in the boundary of $\partial V^\prime W$. The curve $G$ starts at one of the points in the intersection $\alpha_1 \cap \alpha_1'$, following an arc in $\alpha_1'$ to the first point with $r$-coordinate equal to 2, then follows the arc $L_1^- \cap \{r = 2\}$, and finally follows the curve $\alpha_1'$ to the other point in $\alpha_1 \cap \alpha_1'$. Thus, the curve $G$, as illustrated in Figure 12, is composed of three smooth arcs, where the first and last are contained in $\alpha_1'$ and satisfy the radial monotonicity assumption in Section 11, and the middle arc lies on a segment of the circle $\{r = 2\}$, so is tangent in its interior to the curve $\Gamma$ at $\sigma_1^{-1}(p_1)$ as illustrated in Figure 42. Note that $G$ bounds a region in $L_1^-$ that contains the pre-image of the set $E_{1}^{-,+}$ under the insertion map $\sigma_1$. We define the curve $L \subset L_2^-$ using the curve $\alpha_2'$ in the analogous manner, with details omitted.

![Figure 42. The curve $G$ in $L_1^-$](image)

Next, we form two infinite propellers by considering the flow under $W$ of the curves $G$ and $L$, as for the curves $\Gamma$ and $\Lambda$ in Section 11. The $\Psi_t$-flow of the middle arc in $G$ is an infinite strip which spirals around the cylinder $C = \{r = 2\}$ in the region $\{-2 < z < -1\}$, and contains the spiraling curve $\Sigma_1^- = \{\Psi_t(\sigma_1^{-1}(p_1^-)) \mid t \geq 0\}$ in the interior of the strip. Let $\overline{G} \subset L_1^+$ be the facing curve to $G$, then similar observations apply to the reverse $\Psi_t$-flow of $\overline{G}$ and the spiraling curve $\overline{\Sigma}_1^+ = \{\Psi_t(\sigma_1^{-1}(p_1^+)) \mid t \leq 0\}$. The $\psi_t$-flow of the two arcs of $G$ which are contained in $\alpha_1'$ generate two infinite propellers. Form the infinite double propeller $\mathcal{P}_G \subset W$ from the union of these two propellers and the two infinite strips. Then $P_G$ contains $\overline{Z}_1^- = Z_1^- \cup Z_1^+$ defined in (39).

Let $P_L$ be the infinite double propeller corresponding to $L$ defined in the same way, which then contains $\overline{Z}_1^- = Z_1^- \cup Z_1^+$. As the curves $G$ and $L$ are disjoint, the propellers $P_G$ and $P_L$ are also disjoint. We then have the analogous result to Proposition 11.2.

**Proposition 16.2.** The closures $\overline{\mathcal{P}}_G$ and $\overline{\mathcal{P}}_L$ of the infinite propellers $P_G$ and $P_L$ contain the Reeb cylinder $\mathcal{R}$, and we have

$$\overline{\mathcal{P}}_G = P_G \cup \mathcal{R}, \quad \overline{\mathcal{P}}_L = P_L \cup \mathcal{R}.$$

**Proof.** Let $\{x_n \in P_G \mid n = 1, 2, \ldots\}$ converge to a point $x_*$. If $r(x_*) > 2$, then we can assume that $r(x_n) > 2$ and as the Wilson flow preserves the radius coordinate $r$, there is a corresponding sequence of points $\{y_n \in \alpha_1' \cap G \subset L_1 \mid n = 1, 2, \ldots\}$, with $r(y_n) = r(x_n)$ and $y_n, x_n$ in the same $W$-orbit. Then $r(y_n) \to r(x_*) > 2$, so $x_* \in P_G$. In the case that $r(x_*) = 2$, then the sequence $\{y_n\}$ converges is either in $G$ or in $\overline{G}$. Assuming it
belongs to \( G \), it converges to a point in \( G \cap \{ r = 2 \} \). The forward Wilson flow of these points converge to the periodic orbit \( O_1 \). Then the points \( x_n \) converge to a point in the cylinder \( \mathcal{R} \), so \( x_n \in \mathcal{R} \). A similar argument holds for the backward Wilson flow of the facing curve \( \alpha_i \), for which the inner endpoints limit on the periodic orbit \( O_2 \).

The analysis of the closure of the propeller \( P_L \) proceeds similarly. \( \square \)

Observe that \( G \) divides \( \partial_h^− \mathcal{W} \) into two open regions. Let \( \mathcal{U} \) denote the region in the complement of \( G \) which is contained in \( L_1^− \), so that points in \( \mathcal{U} \) have \( r \)-coordinate bigger than 2. Let \( \mathcal{W} \) denote the open region in \( \mathcal{W} \) obtained from the \( \Psi_t \)-flow of \( \mathcal{U} \) from \( L_1^− \) to \( L_1^+ \). It follows that \( P_G \) is contained in the closure of \( \mathcal{U} \), and so \( \overline{P_G} \subset \overline{\mathcal{U}} \). Since \( \Gamma \) is contained in the closure of \( \mathcal{U} \) and \( \Gamma \setminus \{ \alpha_i^−(p_1^+) \} \) is contained in \( \mathcal{U} \), we conclude that \( \overline{P_{\Gamma_1} - \mathcal{Z}_2} \subset \mathcal{U} \) as well. We say that the double propeller \( P_G \) envelops the double propeller \( P_{\Gamma_1} \).

Similarly, let \( \mathcal{V} \) denote the region in the complement of \( L \) which is contained in \( L_2^− \), so that points in \( \mathcal{V} \) have \( r \)-coordinate bigger than 2. Let \( \mathcal{V} \) denote the open region in \( \mathcal{W} \) obtained from the \( \Psi_t \)-flow of \( \mathcal{V} \) from \( L_2^− \) to \( L_2^+ \). Then \( P_L \) is contained in the closure of \( \mathcal{V} \), and \( \overline{P_L} \subset \overline{\mathcal{V}} \). Correspondingly, we say that \( P_L \) envelops \( P_{\Lambda} \).

Next, consider the notched double propellers

\[
P'_G = P_G \cap \mathcal{W} \quad \text{and} \quad P'_L = P_L \cap \mathcal{W}.
\]

Since \( \mathcal{Z}_2 \subset P_G \), the propeller \( P'_G \) intersects \( L_1^− \) infinitely many times, once for each intersection of the \( \mathcal{W} \)-orbit of the special point \( \alpha_i^−(p_1^+) \) with \( L_1^− \). In the same way, \( P'_G \) intersects \( L_2^− \) infinitely many times.

For each \( i = 1, 2 \), the intersections \( P_G \cap L_1^− \) and \( P_G \cap L_2^− \) form two infinite collections of curves \( G'(i, \ell) \) and \( L'(i, \ell) \), respectively, for \( b \leq \ell \) and unbounded. Apply \( \sigma_i^− \) to these curves, to obtain in \( L_1^− \cup L_2^− \subset \partial_h^− \mathcal{W} \), four countable collections of curves labeled, for \( b \geq 0 \), as illustrated in Figure 43.

- \( G(1, \ell) \) tangent at \( p(1; 1, \ell) \) to \( \Gamma(1, \ell) \) in \( L_1^− \);
- \( L(1, \ell) \) tangent at \( p(2; 1, \ell) \) to \( \Lambda(1, \ell) \) in \( L_1^− \);
- \( G(2, \ell) \) tangent at \( p(1; 2, \ell) \) to \( \Gamma(2, \ell) \) in \( L_2^− \);
- \( L(2, \ell) \) tangent at \( p(2; 2, \ell) \) to \( \Lambda(2, \ell) \) in \( L_2^− \).

For \( b < \ell < 0 \) as introduced in Section 12 and illustrated in Figure 40, the curves \( G'(i, \ell) \) and \( L'(i, \ell) \) have two connected components, which follows from the discussion in Section 11. As in Proposition 15.4.1 the bubbles generated by these curves have uniformly bounded level difference, and thus do not change the discussion below. Thus, without loss of generality we assume for the rest of the section that \( b = 0 \).

Observe that since the \( \Psi_t \)-flow of the middle arc in \( G \) spirals around the cylinder \( C \cap \{ z < -1 \} \), it intersects the interval \( J_0 \) defined in (64) in a sequence of closed intervals. Hence each curve \( G(1, \ell) \) contains a closed arc contained in \( \kappa \subset \Gamma \), for \( \kappa \) as defined in (63). In the same way, each curve \( L(1, \ell) \) has an arc in \( \kappa \). Similarly, each of the curves \( G(2, \ell) \) and \( L(2, \ell) \) intersects \( \chi \subset \Lambda \) along a closed arc.

The endpoints of each one of the \( G(i, \ell) \) and \( L(i, \ell) \) curves are contained in the boundary of \( \partial_h^− \mathcal{W} \), while the middle arcs are in \( \kappa \) or \( \chi \), accordingly. By flowing these curves in \( \mathcal{W} \), we obtain four countable collections of finite double propellers, denoted by \( P_{G(i, \ell)} \) and \( P_{L(i, \ell)} \). The curves \( G(i, \ell) \) and \( L(i, \ell) \) do not satisfy the radial monotonicity assumption in Section 11. However, the two arcs that are not contained in \( \kappa \) or \( \chi \), are endpoint isotopic to a curve satisfying the transversality condition, hence the conclusion that each of the curves \( G(i, \ell) \) and \( L(i, \ell) \) separates the region \( L_i^− \) into two open regions remains true. The finite double propellers \( P_{G(i, \ell)} \) and \( P_{L(i, \ell)} \) are isotopic to a standard finite double propeller and separate \( \mathcal{W} \) into two connected components.

Continue the above process recursively, to obtain collections of curves

- \( G(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \subset L_1^− \subset \partial_h^− \mathcal{W} \), tangent to \( \Gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \) at \( p(1; i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \);
- \( L(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \subset L_2^− \subset \partial_h^− \mathcal{W} \), tangent to \( \Lambda(i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \) at \( p(2; i_1, \ell_1; i_2, \ell_2; \cdots; i_n, \ell_n) \).
Let \( n \) be the corresponding notched propellers.

We next discuss topological properties of the families of propellers formed from the \( G \) and \( L \) curves. Recall that the points \( p(1; i_1, i_2, \ell_2; \cdots ; i_n, \ell_n) \) divide the parabolic \( \Gamma \)-curves in two arcs,

\[
\Gamma(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) = \gamma(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \cup \kappa(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n).
\]

The level \( n \) curve \( \Gamma(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) is tangent at \( p(1; i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) to a level \( n-1 \) curve. For \( i_1 = 1 \), it is tangent to the curve \( \Gamma(\ell_2; \cdots ; i_n, \ell_n) \) and

\[
p(1; i_1, 1; i_2, \ell_2; \cdots ; i_n, \ell_n) \text{ belongs to } \kappa(i_2, \ell_2; \cdots ; i_n, \ell_n).
\]

For \( i_2 = 2 \) the curve \( \Gamma(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) is tangent to the curve \( \Lambda(i_2, \ell_2; \cdots ; i_n, \ell_n) \) and

\[
p(1; i_1, i_2, \ell_2; \cdots ; i_n, \ell_n) \text{ belongs to } \chi(i_2, \ell_2; \cdots ; i_n, \ell_n).
\]

Thus:

- \( p(1; 1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) and \( p(2; 1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) lie in \( \kappa(i_2, \ell_2; \cdots ; i_n, \ell_n) \) for any \( \ell_1 \);
- \( p(1; 2, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) and \( p(2; 2, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \) lie in \( \chi(i_2, \ell_2; \cdots ; i_n, \ell_n) \) for any \( \ell_1 \).

**Lemma 16.3.** Any two distinct \( G \) and \( L \) curves of the collection above, contained in \( L_1^- \cup L_2^- \), are disjoint.

**Proof.** The curve \( \Gamma \) divides \( L_1^- \) in two regions, one of which is contained in \( U \) and its closure contains all the \( \Gamma(1, \ell) \) and \( \Gamma(1, \ell) \) curves. The closure of this region intersects \( G \) only at the special point \( \sigma_1^{-1}(p_1) \). Hence, \( G \) is disjoint from all \( G(1, \ell) \) and \( L(1, \ell) \). In the same way, \( L \) is disjoint from all \( G(2, \ell) \) and \( L(2, \ell) \). Thus, we proceed inductively, to obtain that any two different curves in the collection of \( G \) and \( L \) curves are disjoint. \( \square \)

We now consider the intersection of the notched propellers

\[
P_G'(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n) \quad P_L'(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n)
\]

with the rectangle \( R_0 \). Following the notation convention developed in Section 13, \( R_0 \) is a countable collection of closed curves, labeled \( G_0(\ell) \) and \( L_0(\ell) \), as illustrated in Figure 44. Observe that for each \( \ell \geq a \), where \( a \leq 0 \) was defined in Remark 13.3, the curve \( G_0(\ell) \) contains a segment of
In each \( J_0 \), a segment of \( K_0 \), and is tangent at the two points \( p_0(1; i, \ell) \) to the curve \( \Gamma_0(\ell) \) for \( i = 1, 2 \). In the same way, each \( L_0(\ell) \) contains a segment of \( J_0 \), a segment of \( K_0 \) and is tangent at the two points \( p_0(2; i, \ell) \) to the curve \( \Lambda_0(\ell) \) for \( i = 1, 2 \).

Each \( G_0(\ell) \) curve divides \( R_0 \) in two open connected regions, one of which contains \( \Gamma_0(\ell) \) and is contained in \( U \cap R_0 \). We call this region the interior of \( G_0(\ell) \) and we denote it by \( U_0(\ell) \). Analogously, the interior of each \( L_0(\ell) \) is denoted by \( V_0(\ell) \).

As in the previous section, we define families of \( G_0 \) and \( L_0 \) curves in \( R_0 \cap \{ r \geq 2 \} \) recursively.

Recall that \( U \) denotes the interior region of \( P_G \subset W \), so that \( U \) as defined previously satisfies \( U = U \cap \partial_h^{-}W \subset L_1^{-} \). Also, \( V \) denotes the interior region of \( P_L \subset W \), so that \( V \) as defined previously satisfies \( V = V \cap \partial_h^{-}W \subset L_2^{-} \).

In a corresponding manner, for the families of \( G \) and \( L \) curves, let \( U(i_1, \ell_1; \cdots; i_n, \ell_n) \) denote the interior region of \( P_{G(i_1, \ell_1; \cdots; i_n, \ell_n)} \subset W \), and \( V(i_1, \ell_1; \cdots; i_n, \ell_n) \) denote the interior region of \( P_{L(i_1, \ell_1; \cdots; i_n, \ell_n)} \subset W \). Then we define open regions in \( \partial_h^{-}W \) as follows:

\[
(81) \quad U(i_1, \ell_1; \cdots; i_n, \ell_n) = U(i_1, \ell_1; \cdots; i_n, \ell_n) \cap \partial_h^{-}W
\]

\[
(82) \quad V(i_1, \ell_1; \cdots; i_n, \ell_n) = V(i_1, \ell_1; \cdots; i_n, \ell_n) \cap \partial_h^{-}W.
\]

The intersection of the regions \( U(i_1, \ell_1; \cdots; i_n, \ell_n) \) and \( V(i_1, \ell_1; \cdots; i_n, \ell_n) \) with \( R_0 \) form two finite collections of connected open regions, which are indexed as follows:

\[
(83) \quad U_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset \tau(U(i_1, \ell_1; \cdots; i_n, \ell_n) \cap R_0), \quad \ell_{n+1} \geq a
\]

\[
(84) \quad V_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset \tau(V(i_1, \ell_1; \cdots; i_n, \ell_n) \cap R_0), \quad \ell_{n+1} \geq a,
\]

which extends the notation convention introduced above for \( U_0(\ell) \) and \( V_0(\ell) \). Observe that the index \( \ell_{n+1} \) admits finitely many values since the boundary propellers \( P_{G(i_1, \ell_1; \cdots; i_n, \ell_n)} \) and \( P_{L(i_1, \ell_1; \cdots; i_n, \ell_n)} \) are finite.

The forward \( \Psi_t \)-flow of the region in (83) to \( L_1^{-} \) yields the region \( \sigma_1(U(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1})) \subset L_1^{-} \), and its forward \( \Psi_t \)-flow to \( L_2^{-} \) yields the region \( \sigma_2(U(i_1, \ell_1; \cdots; i_n, \ell_n; 2, \ell_{n+1})) \subset L_2^{-} \). Similar comments apply to the regions in (84).

Recall from Lemma \ref{16.3} that the collection of all \( G \) and \( L \) curves in \( \partial_h^{-}W \) are disjoint. This implies a containment property between their interior regions:

**Lemma 16.4.** Suppose that either

- \( U_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \cap U_0(i'_1, \ell'_1; \cdots; i'_{n'}, \ell'_{n'+1}) \neq \emptyset \),
- \( U_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \cap V_0(i'_1, \ell'_1; \cdots; i'_{n'}, \ell'_{n'+1}) \neq \emptyset \),
- \( V_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \cap V_0(i'_1, \ell'_1; \cdots; i'_{n'}, \ell'_{n'+1}) \neq \emptyset \),

then \( n' \neq n \) and \( \ell_{n+1} = \ell'_{n'+1} \).

If \( n' > n \), let \( n' = n + m \). Then \( U_0(i'_1, \ell'_1; \cdots; i'_{n'}, \ell'_{n'+1}) \) is contained in

- \( U_0(i_1, \ell_1; \cdots; i_n, \ell_{n+1}) \) if \( i_{n'-n} = 1 \) and for any \( 1 \leq k \leq n \)

\[
(85) \quad i_k = i'_{k+m} = i'_{(n'-n)+k} \quad \text{and} \quad \ell_k = \ell'_{k+m} = \ell'_{(n'-n)+k}.
\]

- \( V_0(i_1, \ell_1; \cdots; i_n, \ell_{n+1}) \) if \( i_{n'-n} = 2 \) and for any \( 1 \leq k \leq n \)

\[
(86) \quad i_k = i'_{k+m} = i'_{(n'-n)+k} \quad \text{and} \quad \ell_k = \ell'_{k+m} = \ell'_{(n'-n)+k}.
\]

The same conclusions hold for \( V_0(i'_1, \ell'_1; \cdots; i'_{n'}, \ell'_{n'+1}) \).

**Proof.** The boundaries of the \( U_0 \) and \( V_0 \) regions are disjoint by Lemma \ref{16.3}, so the inclusion of one into the other follows, if the regions are not disjoint. The identities (85) and (86) involving the indices follow from the construction of the curves.

\[\square\]
We describe two cases to illustrate the conclusion of Lemma 16.4.

- For $i_1 = i_2 = 1$, the region $U_0(1, \ell_1; 1, \ell_2; \cdots ; \ell_n)$ is contained in $U_0(1, \ell_2; \cdots ; \ell_n)$ and $U_0(i_3, \ell_3; \cdots ; \ell_n)$.
- For $i_1 = 2, i_2 = 1$, the region $U_0(2, \ell_1; 1, \ell_2; \cdots ; \ell_n)$ is contained in $V_0(1, \ell_2; \cdots ; \ell_n)$ and $U_0(i_3, \ell_3; \cdots ; \ell_n)$.

Observe that each propeller $P_{G(i_1, \ell_1; \cdots ; i_n, \ell_n)}$ envelops the propeller $P_{T(i_1, \ell_1; \cdots ; i_n, \ell_n)}$. This yields a nested relation between the regions bounded by the $G_0$ and $L_0$ curves, and the $G_0$ and $A_0$ curves in $R_0$. This is illustrated in Figure 44 and we describe the relation in two special cases.

- The region $U_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ contains the curve $\Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ in its interior, and the intersection of the two associated curves consists of the points

$$G_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n) \cap \Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n) = p_0(1; i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n), \quad i_n = 1, 2.$$

For $i_1 = 1$, the curve $G_0(1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ intersects $\kappa_0(i_2, \ell_2; \cdots ; \ell_n)$ in two closed arcs, one containing $p_0(1; 1, \ell_1; i_2, \ell_2; \cdots ; 1, \ell_n)$, and the other containing $p_0(1; 1, \ell_1; i_2, \ell_2; \cdots ; 2, \ell_n)$.

For $i_1 = 2$, the curve $G_0(2, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ intersects $\chi_0(i_2, \ell_2; \cdots ; \ell_n)$ in two closed arcs, one containing $p_0(1; 2, \ell_1; i_2, \ell_2; \cdots ; 1, \ell_n)$, and the other containing $p_0(1; 2, \ell_1; i_2, \ell_2; \cdots ; 2, \ell_n)$.

- The region $V_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ contains the curve $\Lambda_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ in its interior, and the intersection of the two associated curves consists of the points

$$L_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n) \cap \Lambda_0(i_1, \ell_1; i_2, \ell_2; \cdots ; \ell_n) = p_0(2; i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n), \quad i_n = 1, 2.$$

For $i_1 = 1$, the curve $L_0(1, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ intersects $\kappa_0(i_2, \ell_2; \cdots ; \ell_n)$ in two closed arcs, one containing $p_0(2; 1, \ell_1; i_2, \ell_2; \cdots ; 1, \ell_n)$, and the other containing $p_0(2; 1, \ell_1; i_2, \ell_2; \cdots ; 2, \ell_n)$.

For $i_1 = 2$, the curve $L_0(2, \ell_1; i_2, \ell_2; \cdots ; \ell_n)$ intersects $\chi_0(i_2, \ell_2; \cdots ; \ell_n)$ in two closed arcs, one containing $p_0(2; 2, \ell_1; i_2, \ell_2; \cdots ; 1, \ell_n)$, and the other containing $p_0(2; 2, \ell_1; i_2, \ell_2; \cdots ; 2, \ell_n)$.

![Figure 44](image-url)

**Figure 44.** Endparts of $\Gamma_0$ and $\Lambda_0$ curves inside $G_0$ and $L_0$ curves in $R_0$ (viewed sideways)

With these preparations, we can make the following definition for the points in $R_0$ with $r(x) > 2$, which extends the notion of “level” for those points not contained in $M$. Recall that $M_{R_0} = M \cap R_0$.

**Definition 16.5.** Let $x \in R_0$ with $r(x) > 2$, and $x \not\in M_{R_0}$. Say that $x$ has level at least $n$, and write $L(x) \geq n$, if either there exists an open region $U_0$ or $V_0$ of level $n$ such that $x$ is contained in the closure of either such regions:

$$x \in \bigcup U_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n) \quad \text{or} \quad x \in \bigcup V_0(i_1, \ell_1; \cdots ; i_{n-1}, \ell_{n-1}; \ell_n).$$

The level of $x$ is the greatest $n \geq 1$ such that $L(x) \geq n$. If $L(x) \geq n$ for all $n$, then $x$ is said to have infinite level, and otherwise has finite level. If $x$ is not contained in any such region, set $L(x) = 0$.

The following is a key property of the level.

**Proposition 16.6.** Let $x \in R_0$ with $r(x) > 2$, and $x \not\in M_{R_0}$. Then $x$ has finite level.

**Proof.** Let $G_0$ denote the union of the $G_0$-curves in $R_0$, and $L_0$ the union of the $L_0$-curves. Recall that $M$ is the closure of $M_{R_0}$ which is the union of all $\gamma_0$ and $\lambda_0$ curves in $R_0$.

Set $\mathcal{Y} = M_{R_0} \cup G_0 \cup L_0$. The set $\mathcal{Y}$ is bounded in $R_0$ so its closure is compact, but more is true.
**Lemma 16.7.** The set $\mathcal{Y}$ is closed, hence is compact.

*Proof.* By Proposition 16.2, the limit of curves $G_0(\ell)$ and $L_0(\ell)$ as $\ell \to \infty$ is contained in $\mathcal{Y}$. Thus, for a fixed index $(i_1, *, i_2, \ell_2; \ldots; \ell_n)$, the limit of curves $G_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ or $L_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ as $\ell_1 \to \infty$ is contained in $\mathcal{Y}$.

Given a sequence of points in $\mathcal{Y}$ which are contained in $G_0$ or $L_0$ curves with indices $(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ where the degree $n$ tends to infinity, we observe that the sequence must be nested by Lemma 16.4, and each interior region $U_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ or $V_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ contains a corresponding $\gamma_0$ or $\lambda_0$ which is contained in $\mathcal{M}_0$ hence in $\mathcal{Y}$. It follows that any convergent sequence of points in $\mathcal{G}_0$ or $\mathcal{L}_0$ of this form must have limit in the set $\mathcal{Y}$.

Let $\epsilon > 0$ be chosen small enough, so that $\epsilon < d_{R_0}(x, \mathcal{M}_{R_0})$ for the metric $d_{R_0}$ defined in Section 9. That is, the distance from every point of $\mathcal{M}_{R_0}$ to $x$ is greater than $\epsilon$.

Recall that the $G_0$ and $L_0$ curves in $R_0$ are disjoint closed curves by Lemma 16.3, so for each index there exists an $\epsilon_0 > 0$ (where we abuse notation and do not indicate the precise index on $\epsilon_0$) so that each of the sets

\begin{align}
U_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n, \epsilon_0) &= \{y \in R_0 \mid d_{R_0}(y, G_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)) < \epsilon_0\} \\
V_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n, \epsilon_0) &= \{y \in R_0 \mid d_{R_0}(y, L_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)) < \epsilon_0\}
\end{align}

contains exactly one $G_0$ or $L_0$ curve. We comment on these definitions.

Observe that the curve $G_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ contains the points $p_0(1; i_1, \ell_1; i_2, \ell_2; \ldots; i_n, \ell_n)$ for $i_n = 1, 2$. Since the curves $G_0(1; \ell, i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ limit as $\ell \to \infty$ to $\gamma_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$, for $\ell$ big enough the open set $U_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n, \epsilon_0)$ intersects these curves, but it does not contains them, as illustrated in Figure 45.

![Figure 45](image_url)

**Figure 45.** Lower part of $\Gamma_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$ inside region bounded by $G_0(i_1, \ell_1; i_2, \ell_2; \ldots; \ell_n)$

Form an open covering of $\mathcal{Y}$ which consists of the open neighborhood $U_0(\mathcal{M}, \epsilon)$ of $\mathcal{M}_{R_0}$, and all open sets of the form (87) and (88). Then by Lemma 16.7 there is a finite subcovering, which must consist of $U_0(\mathcal{M}, \epsilon)$ and a finite collection of open sets of the form (87) and (88). It follows that for all but a finite number of
exceptions, the $G_0$ and $L_0$ curves are contained in $U_0(\mathcal{M}, \epsilon)$, and thus the closures of their interiors are also contained in $U_0(\mathcal{M}, \epsilon)$. As $x \notin U_0(\mathcal{M}, \epsilon)$, there are only a finite number of $G_0$ or $L_0$ curves whose interior closures contain $x$. If $L(x) \neq 0$, then $L(x)$ is the maximum value of the level for all such interior regions which contain $x$, which is finite. \hfill \Box

We use now the constructions and results above to describe the dynamical properties of the $\Phi_t$-orbits of points $x \in \mathbb{R}_0$ with $r(x) \geq 2$ and $x \notin \mathcal{M}_{\mathbb{R}_0}$. First, recall that the map $\tau: \mathbb{W} \to \mathbb{K}$ identifies the surfaces $L_1^-$ and $L_2^-$ via the map $\sigma_i$, to yield the entry region $E_i$, for $i = 1, 2$. The map $\sigma_i$ sends $\alpha_i'$ to the arc $\beta_i' \subset \partial^+ \mathbb{W} \setminus (L_1^- \cup L_2^-)$. The points in $\sigma_1(G \cap \alpha_1')$ and $\sigma_2(L \cap \alpha_2')$ are technically secondary entry points of $K$ as defined in Section 4, but can also be considered as primary entry points as they lie in the closure of the primary entry points. The two arcs $\sigma_1(G \cap \{r = 2\})$ and $\sigma_2(L \cap \{r = 2\})$ are exactly the secondary entry points in $E_1$ and $E_2$, respectively, whose $r$-coordinate is equal to 2. The forward orbit of these points has $r$-coordinate bigger or equal to 2 by Corollary 7.3.

**PROPOSITION 16.8.** Suppose that $x \in \mathbb{R}_0$ is not in the $K$-orbit of $\omega_1$ or $\omega_2$, and is contained in a $L_0$ or $G_0$ curve, so that for some index $\{i_1, \ell_1; \ldots; \ell_n\}$ we have

$$x \in G_0(i_1, \ell_1; \ldots; \ell_n) \text{ or } x \in L_0(i_1, \ell_1; \ldots; \ell_n).$$

1. If $x \notin \kappa_0(i_2, \ell_2; \ldots; \ell_n) \cup \chi_0(i_2, \ell_2; \ldots; \ell_n) \cup J_0 \cup K_0$, then there exists $t, t' \in \mathbb{R}$ such that $\Phi_t(x) \in \tau(\beta_i' \times \{2\})$ and $\Phi_{t'}(x) \in \tau(\beta_i' \times \{-2\})$, for $j = 1$ or 2. Hence the orbit of $x$ escapes $\mathbb{K}$ in positive and negative time.

2. If $x \in \kappa_0(i_2, \ell_2; \ldots; \ell_n) \cup \chi_0(i_2, \ell_2; \ldots; \ell_n) \cup J_0 \cup K_0$, then there exists $t \in \mathbb{R}$ such that $y = \Phi_1(x)$ is a transition point with $\rho_y(t) = 2$. If $y$ is a secondary entry point, its forward orbit limits to $\omega_1$, while if $y$ is a secondary exit point its backward orbit limits to $\omega_2$.

**Proof.** We consider the case where $x \in G_0(i_1, \ell_1; \ldots; \ell_n)$, with the case $x \in L_0(i_1, \ell_1; \ldots; \ell_n)$ being analogous.

If $n = 1$, then $x$ is contained in one of the curves $G_0(\ell_1)$, as illustrated in Figure 43. Let $x' = \tau^{-1}(x) \in G_0(\ell_1) \subset \mathbb{R}_0$, then flow backwards in $\mathbb{W}$, to obtain a point $x'_{-1} \in G$, where $G$ is illustrated in Figure 42. As $x$ does not lie on the flow of the special points, the point $x'_{-1}$ lies either on the curve $G \cap \alpha_1'$ with $r(x'_{-1}) > 2$ or in $G \cap \{r = 2\}$. The first case corresponds to (1) and we have that $x'_{-1}$ is a secondary entry point on the boundary of the primary entry points. It follows that the backward $\Phi_t$-orbit of $x_{-1} = \tau(x'_{-1})$ escapes $\mathbb{K}$ in finite time. By Proposition 6.7, the forward $\Phi_t$-orbit of $x_{-1}$ passes through the facing point $\bar{x}_{-1} \in x_{-1} = \tau(x'_{-1})$ and thus the forward orbit exits $\mathbb{K}$ as claimed. The second case corresponds to (2) and $x_{-1}$ is the secondary entry point $y$, whose forward orbit limits to $\omega_1$ by Proposition 7.3.

Next, assume that $n \geq 2$, then $r(x) > 2$. Since $x \in G_0(i_1, \ell_1; \ldots; \ell_n)$ it belongs to the propeller $\tau(P_{G(i_1, \ell_1; \ldots; \ell_{n-1}, \ell_{n-1})})$. Then $x' = \tau^{-1}(x)$ is in the propeller $P_{G(i_1, \ell_1; \ldots; \ell_{n-1}, \ell_{n-1})}$. Flow $x'$ backwards in $\mathbb{W}$, to obtain a point $x'_{-1} \in L_{i_1}^-$, that belongs to the curve $G(i_1, \ell_1; \ldots; \ell_{n-1}, \ell_{n-1})$. By Proposition 6.7, $x_{-1} = \tau(x'_{-1})$ is a secondary entry point in the $K$-orbit of $x$.

The point $x_{-1}$ can be identified with a point $x_{0,-1}^0 \in G_0(i_1, \ell_1; \ldots; \ell_{n-1})$: consider $x_{-1}$ and flow it backwards from $E_{i_1} \to \mathbb{R}_0$. Then $r(x_{0,-1}^0) \geq 2$, and repeat the process inductively to obtain $x_{-1}'(n-1) \in G(i_1, \ell_1; \ldots; \ell_{n-1}, \ell_{n-1})$. We have two possible situations:

1. If $r(x_{0,-1}) > 2$, we have that $x_{0,-1}^0 \in G_0(\ell_1) \setminus (J_0 \cup K_0)$ and

$$x \in G_0(i_1, \ell_1; \ldots; \ell_n) \setminus \kappa_0(i_2, \ell_2; \ldots; \ell_n) \cup \chi_0(i_2, \ell_2; \ldots; \ell_n) \cup J_0 \cup K_0.$$ 

Then the $W$-orbit of $\tau^{-1}(x_{0,-1}^0)$ is finite and intersects $\partial^{-}_{i_1} \mathbb{W}$ in a point $x_{-1}'$ contained in $G \cap \alpha_1'$. Thus $\sigma_1(x_{-1}')$ is in the boundary of the primary entry points of $\mathbb{K}$, implying that the orbit of $x$ escapes in negative time. Since $r(\sigma_1(x_{-1}')) > 2$, the orbit of $x$ escapes in forward time.
(2) If \(r(x^0_{-(n-1)}) = 2\), then either \(z(x^0_{-(n-1)}) < -1\) or \(z(x^0_{-(n-1)}) > 1\) and
\[
x \in G_0(i_1, \ell_1; \cdots; \ell_n) \cap [\kappa_0(i_2, \ell_2; \cdots; \ell_n) \cup \chi_0(i_2, \ell_2; \cdots; \ell_n) \cup J_0 \cup K_0].
\]
Assume first that \(z(x^0_{-(n-1)}) < -1\), or equivalently that \(x^0_{-(n-1)} \in J_0\). Consider the point \(\tau^{-1}(x^0_{-(n-1)})\) and flow it backwards in \(\mathbb{W}\). We obtain an entry point \(x'_{-n}\) in \(G \cap \{r = 2\}\) and \(\sigma_1(x'_{-n})\) is a secondary entry point with \(r\)-coordinate equal to 2 in the \(K\)-orbit of \(x\). By Proposition 7.1, its forward \(K\)-orbit accumulates on \(\omega_1\).

If on the contrary \(z(x^0_{-(n-1)}) > 1\), or equivalently that \(x^0_{-(n-1)} \in K_0\), consider the point \(\tau^{-1}(x^0_{-(n-1)})\) and flow it forward in \(\mathbb{W}\). We obtain an exit point \(x''_{-n}\) in \(G \cap \{r = 2\}\) and \(\sigma_1(x''_{-n})\) is a secondary exit point with \(r\)-coordinate equal to 2 in the \(K\)-orbit of \(x\). By Proposition 7.1, its backward \(K\)-orbit accumulates on \(\omega_2\). \(\square\)

We next investigate the behavior of the \(K\)-orbit of points in \(R_0\) with \(r\)-coordinate bigger than 2 that do not belong to \(\mathbb{J}\).

**PROPOSITION 16.9.** Let \(x \in R_0\) with \(r(x) > 2\), assume that \(x \notin \mathbb{J}\). Let \(0 \leq L(x) < \infty\) be the level of \(x\), as defined in Definition 16.5. Then we have the following possibilities:

1. Let \(L(x) = 0\), so that \(x\) is outside every \(G_0\) and every \(L_0\) curve, then \(\rho_x(t) > 2\) for all \(t\), and the orbit of \(x\) escapes \(\mathbb{K}\) in positive and negative time.

2. Let \(L(x) = n > 0\), so that \(x\) is contained in an open \(U_0\) or \(V_0\) region of level \(n\), and assume that \(x\) is also in the interior of the corresponding \(\Gamma_0\) or \(\Lambda_0\) curve whose vertex lies on the boundary of the region. Then \(\rho_x(t) > 2\) for all \(t\), and the orbit of \(x\) escapes \(\mathbb{K}\) in positive and negative time.

3. Let \(L(x) = n > 0\), and assume that \(x\) lies in the interior of \(U_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\) and in the exterior of \(\Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\), then there exist \(s < 0\) such that \(\Phi_s(x)\) is a secondary entry point, and for \(\epsilon > 0\) sufficiently small we have \(\rho_x(s - \epsilon) < 2\).

4. Let \(L(x) = n > 0\), and assume that \(x\) lies in the interior of \(V_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\) and in the exterior of \(\Lambda_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\), then there exist \(s < 0\) such that \(\Phi_s(x)\) is a secondary entry point, and for \(\epsilon > 0\) sufficiently small we have \(\rho_x(s - \epsilon) < 2\).

**Proof.** Let \(x' \in R_0 \subset \mathbb{W}\) such that \(x = \tau(x')\). By assumption, \(r(x') > 2\) thus its Wilson orbit contains an entry point \(x'_{-1} \in \partial^* \mathbb{W}\) with \(r(x'_{-1}) = r(x) > 2\). Then Proposition 6.7 implies that \(\tau(x'_{-1}) = x_{-1}\) is in the \(K\)-orbit of \(x\). If \(x_{-1}\) is a secondary entry point, we find \(x''_{-1} \in R_0\) by flowing \(x_{-1}\) backwards. If \(r(x''_{-1}) > 2\) we can repeat this process for as long as these conditions are satisfied. This reverse flow process stops when either \(x_{-n}\) is a primary entry point, or \(r(x^0_{-(n-1)}) \leq 2\).

We now analyze the four cases in the theorem:

1. Since \(x\) is outside every \(G_0\) and every \(L_0\) curve, \(x'_{-1} \in \partial^* \mathbb{W} \setminus (L^+_1 \cup L^-_1)\) and hence \(x_{-1}\) is a primary entry point in the \(K\)-orbit of \(x\) with \(r(x_{-1}) = r(x) > 2\). Then Proposition 6.5 implies that \(\rho_x(t) > 2\) for all \(t\), and that the orbit of \(x\) escapes \(\mathbb{K}\) in positive and negative time.

2. We discuss the case where \(x\) is contained in a \(U_0\) region. The alternate case where \(x\) is contained in a \(V_0\) region follows similarly. The assumption that \(L(x) = n\), and that \(x\) does not belong to any \(G_0\) or \(L_0\) curve, implies there is a unique region with \(x \in U_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\). It follows that \(x\) is contained in the interior of the curve \(\Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)\), which is a connected component of the intersection of \(\tau(P^x(i_1, i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1}) \cap R_0)\). It then follows that the point \(x'_{-1}\) constructed above lies inside the region bounded by the curve \(\Gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1}) \subset L^-_{i_{n-1}}\). Thus, \(x^0_{-1}\) is in the interior of \(\Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_{n-1})\), and we have that \(r(x^0_{-(n-1)}) > 2\).
We repeat the process recursively $n - 1$ times, to obtain $x_{-(n-1)}^0 \in R_0$ with $r(x_{-(n-1)}^0) > 2$ and contained in the interior of $\Gamma_0(\ell_1)$. The assumption that $L(x) = n$ implies that $x_{-(n-1)}^0$ lies in the exterior of each $G_0(1, k; \ell_1)$ and $L_0(1, k; \ell_1)$ curve, for any $n \leq k < \infty$.

The backward $W$-orbit of $x_{-(n-1)}^0$ yields the entry point $x_{-n}^r \in \partial_h W$. Observe that $r(x_{-n}^r) > 2$ since the Wilson flow preserves the radius, and $x_{-n}^r$ is in the region inside $\Gamma$. Hence $r(x_{-n}^r) \in E_1 \cap \{ r > 2 \}$ and the backward $K$-orbit of this point to $R_0$ yields the point $x_{-n}^0$. Then $r(x_{-n}^0) > 2$ and $x_{-n}^0$ is outside every $G_0$ and $L_0$ curve, so by case (1) we conclude that $\rho_x(t) > 2$ for all $t$, and the orbit of $x$ escapes $K$ in positive and negative time.

(3) Since $G_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_n)$ is in the intersection of $\tau(P'_{G(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1})} \cap R_0$, the point $x_{-1}^0 \in L_{i_{n-1}}^{-}$ is in the region between the curves

$$G(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1}) \text{ and } \Gamma(i_1, \ell_1; i_2, \ell_2; \cdots; i_{n-1}, \ell_{n-1}).$$

Thus, $x_{0}^0$ is in the region between the curves

$$G_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_{n-1}) \text{ and } \Gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots; \ell_{n-1}),$$

from which it follows that $r(x_{-1}^0) > 2$.

We repeat the process recursively $n - 1$ times to obtain $x_{-(n-1)}^0 \in R_0$ in the region between the curves $G_0(\ell_1)$ and $\Gamma_0(\ell_1)$. Then $r(x_{-(n-1)}^0) > 2$ and the entry point $x_{-n}^r$ of its $W$-orbit has radius bigger than 2. Moreover, since $G_0(\ell_1)$ is in the intersection of the propeller $P'_{G_0} \cap R_0$, we conclude that $x_{-n}^r \in U \subset L_1^{-}$. Analogously, $x_{-n}^r$ is outside the curve $\Gamma \subset L_1^{-}$. Hence $x_{-n}$ is a secondary entry point with $r(x_{-n}) > 2$. Then by the definition of the curve $\Gamma$, for $\epsilon > 0$ small $\Phi_{-\epsilon}(x_{-n})$ has $r$-coordinate less than 2. Since $x_{-n}$ is in the backward $K$-orbit of $x$, there exists $s < 0$ be such that $\Phi_s(x) = x_{-n}$ and the conclusion follows.

(4) The proof of this case proceeds exactly as for case (3). 

We next give applications of the properties of $G-L$ curves as developed in this section, to the study of the trapped orbits of points $x \in \mathbb{K}$ in the complement of the compact subspace $\mathcal{M}$.

**Proposition 16.10.** Let $x \in \mathbb{K}$ such that $x \notin \mathcal{M}$ and $\rho_x(t) > 2$ for all $t$. Then the orbit of $x$ escapes $\mathbb{K}$ in positive and negative time.

**Proof.** Let $x \in \mathbb{K}$ with $x \notin \mathcal{M}$ and $r(x) > 2$. If the forward $K$-orbit of $x$ exits $\mathbb{K}$ through an exit point $z$, by hypothesis $r(z) > 2$. Hence the $K$-orbit of $x$ escapes $\mathbb{K}$ in positive and negative time by Proposition 6.5. Thus, we need to consider the case where the forward $K$-orbit of $x$ is trapped.

Now assume that the forward $K$-orbit of $x$ is trapped, then Proposition 7.9 implies that there exists a subsequence $\{x_{i_{\ell}} \mid i_{\ell} = 1, 2, \ldots\} \subset R_0$ such that $\lim_{i_{\ell} \to \infty} r(x_{i_{\ell}}) = 2$. Hence we can assume that the forward $K$-orbit of $x$ intersects $R_0$ in a point $x_1$ with $r(x_1) > 2$ and arbitrarily close to 2.

By hypothesis, $x \notin \mathcal{M}$ which implies that $x_1 \notin \mathcal{M} \cap R_0$, so there exists $\epsilon > 0$ such that the open ball $B_{R_0}(x_1, \epsilon) \subset R_0$ about $x_1$ is disjoint from $\mathcal{M} \cap R_0$, and hence is disjoint from every $\gamma_0$ and $\lambda_0$ curve. Moreover, since $\rho_x(t) > 2$ for all $t$, then we can choose $\epsilon$ such that $B_{R_0}(x_1, \epsilon)$ is disjoint from every $\Gamma_0$ and $\Lambda_0$ curve.

Then $x_1$ satisfies either the hypothesis of Proposition 16.8.1, the hypothesis of Proposition 16.9.1, or the hypothesis of Proposition 16.9.2. In any case, the $K$-orbit of $x_1$ escapes $\mathbb{K}$ in positive and negative time, contradicting the assumption that the forward $K$-orbit of $x$ is trapped.

Recall that the Matsumoto region for a Matsumoto constant $\delta_M > 0$, as defined in Definition 7.4, is the set $\mathcal{U}(\delta_M) = \{ y' \in \mathcal{W} \mid 2 - \delta_M < r(y') < 2 \} \subset \mathbb{K}$. We use the above results to describe the intersection of the $\Phi_t$-flow of the Matsumoto region $\mathcal{U}(\delta_M)$ with the rectangle $R_0$, in terms of the $G_0$ and $L_0$ curves introduced above.
PROPOSITION 16.11. Suppose that $x \in U(\delta_M) \subset \mathbb{K}$ is a secondary entry point, with $y' \in (L_1^- \cup L_2^-)$ and $x' \in (L_1^- \cup L_2^-)$ such that $\tau(y') = \tau(x') = x$. Assume that $2 - \delta_M < r(y') < 2$ and $r(x') > 2$.

(1) If $z(y') < -1$, then the forward orbit of $x$ is trapped, and the points in the intersection of its forward orbit and $R_0 \cap \{r \geq 2\}$ are in the regions between $G_0(i_1, \ell_1; \cdots; \ell_n)$ and $\kappa_0(i_1, \ell_1; \cdots; \ell_n)$, for any collection of indices.

(2) If $z(y') > 1$, then the backward orbit of $x$ is trapped and the points in the intersection of its backward orbit and $R_0 \cap \{r \geq 2\}$ are in the regions between $L_0(i_1, \ell_1; \cdots; \ell_n)$ and $\chi_0(i_1, \ell_1; \cdots; \ell_n)$, for any collection of indices.

(3) If $-1 < z(y') < 1$, then the orbit of $x$ is an infinite orbit and the points in the intersection of its orbit and $R_0 \cap \{r \geq 2\}$ are in the regions between $L_0(i_1, \ell_1; \cdots; \ell_n)$ and $\chi_0(i_1, \ell_1; \cdots; \ell_n)$, for any collection of indices.

Proof. The first conclusion in each item above, that the orbit of $x$ is trapped, follows from the corresponding case of Proposition 16.9.3. For the other cases, we analyze cases as follows.

(1) If $z(y') < -1$, then $x'$ is in the open region of $L_1^-$ bounded by $G$ and $\kappa$. The conclusion then follows by Proposition 16.9.3.

(2) If $z(y') > 1$, then $x'$ is in the open region of $L_2^-$ bounded by $L$ and $\chi$. The conclusion then follows by Proposition 16.9.4.

(3) The case $z(y') = 0$ is impossible for a secondary entry point, by the assumptions on the insertion maps. If $-1 < z(y') < 0$, then $x'$ is in the open region of $L_1^-$ bounded by $G$ and $\gamma$. If $0 < z(y') < 1$, then $x' \in L_2^-$ in the open region bounded by $L$ and $\lambda$. The conclusion then follows by Propositions 16.9.3 and 16.9.4. □

We conclude this section with the proof of Theorem 16.1. Recall that we assume $x \not\in \mathfrak{M}$.

First, if $x$ is a primary entry or exit point, then $x \in \mathfrak{M}$ by Lemma 8.5. In particular, $x \in \mathfrak{M}$ for every $x$ whose $K$-orbit is finite. Thus, we need only consider the case for $x$ such that its $K$-orbit is infinite. We analyze cases, based on the behavior of the radius function $\rho_x(t) = r(\Phi_x(x))$.

If $x$ satisfies $\rho_x(t) > 2$ for all $t \in \mathbb{R}$, then $x$ has finite orbit by Proposition 16.10 so $x \in \mathfrak{M}$.

If $\rho_x(t) < 2$ for some $t \in \mathbb{R}$, then $x$ is wandering by Proposition 8.7 and hence $x \in \mathfrak{M}$.

The final case to consider is when $x$ is an infinite orbit with $\rho_x(t) \geq 2$ for all $t$. Then there is a point $y \in R_0$ on the orbit of $x$, with $r(y) = 2$. As $y \not\in \mathfrak{M}$, it must lie in the interior of one of the segments $J_0$ or $K_0$ in $[54]$. Choose an open neighborhood $U(y, \epsilon)$ for $\epsilon > 0$ sufficiently small, which is disjoint from $\mathfrak{M}$.

If $y$ does not lie in one of the $G_0$ or $L_0$ curves, as illustrated in Figure 42, then we can assume that $U(y, \epsilon)$ is disjoint from these curves. Consider the cases for the orbit of $z \in U(y, \epsilon) \cap R_0$. If $r(z) < 2$ then $z$ is wandering by Proposition 8.7. For $r(z) \geq 2$, then the point $z$ is outside any $G_0$ or $L_0$ curve. Proposition 16.9 implies that the $K$-orbit of $z$ is finite. Thus, $y \in \mathfrak{M}$ and hence $x \in \mathfrak{M}$.

If $y$ is contained in one of the $G_0$ or $L_0$ curves, it is in a level 1 curve. For $z \in U(y, \epsilon) \cap R_0$ we need only consider the case when $r(z) \geq 2$. If $r(z) = 2$ then Proposition 16.8 implies its $W$-orbit is asymptotic to a special point $\omega$. If $r(z) > 2$, then either $z$ is in $L_0(\ell)$ and outside $I_0(\ell)$ for some $\ell$, or $z$ is in $V_0(\ell)$ and outside $A_0(\ell)$ for some $\ell$, thus Proposition 16.9.3 or 16.9.4 applies. Then the orbit of $z$ has points with $r$-coordinate less than 2 and thus is a wandering point by Proposition 8.7.

This covers the possible cases, showing that $\mathbb{K} - \mathfrak{M} \subset \mathfrak{M}$, which is the assertion of Theorem 16.1.

In the next section, we give a condition that implies no points of $\mathfrak{M}$ are wandering, hence $\mathbb{K} - \mathfrak{M} = \mathfrak{M}$. 

94 STEVEN HURDER AND ANA RECHTMAN
17. The minimal set for generic flows

The construction of the flow $\Phi_t$ on the Kuperberg plug $K$ involves various choices, in particular the choice of the vector field $W$ on $W$ satisfying the hypotheses in Section 2 and the choice of the insertions $\sigma_i$ satisfying the hypotheses in Section 3. For any such choice, the $\Phi_t$-flow preserves the compact set $M$ defined by the closure of the orbits of the Reeb cylinder $R$. In this section, we consider an additional regularity hypothesis on the insertion maps $\sigma_i$, which is a uniform version of Hypothesis 12.1 and is used to estimate the behavior of the flow $\Phi_t$ near the special orbits of $\Phi_t$.

We say that $\Phi_t$ is generic if it satisfies the hypotheses in Definition 17.3. The main result of this section is:

**THEOREM 17.1.** If the flow $\Phi_t$ is generic, then $\Sigma = M$.

The proof of Theorem 17.1 will occupy the remainder of this section, and requires a detailed metric analysis of the orbit structure of the $\Psi_t$-flow near the Reeb cylinder $R$, which is used to obtain estimates on the $\Phi_t$-flow near the special orbits.

The equality $\Sigma = M$ has been previously observed in special cases. Ghys gave an argument in Théorème, p. 302] that this conclusion holds for certain generic classes of insertions. The Kuperbergs constructed in [28], an example using polynomial vector fields for which they sketch the proof of that $\Sigma = M$. Our result, which is motivated by these examples, yields this conclusion in more generality. The proof makes full use of the body of techniques developed in this paper, and especially of the properties of the system of double propellers constructed in Section 13. For the more general case of the construction of flows on $K$ which do not satisfy the generic regularity hypotheses, it seems possible that the inclusion $\Sigma \subset M$ may be proper, as discussed in [28], in which case, the minimal set $\Sigma$ will be a “Denjoy-type” invariant set for a flow on a surface lamination.

The additional hypotheses is formulated using the notation of Hypothesis 12.1 on the insertion maps $\sigma_i$ for $i = 1, 2$. The projection along the $z$-coordinate in $W$ is denoted by $\pi_z(r, \theta, z) = (r, \theta, -2)$, and we assume that $\sigma_i$ restricted to the face, $\sigma_i : L_i^- \to W$, has image transverse to the vertical fibers of $\pi_z$. This condition is implicit in the illustrations Figures [6, 8, 9]. Given this assumption, there is a well-defined inverse map $\vartheta_i = (\pi_z \circ \sigma_i)^{-1} : D_i \to L_i^-$ with domain $D_i \subset \partial_h W$, which we recall was given in coordinates in (43) by

$$\vartheta_i(r', \theta', -2) = (R_{i,r}(\theta'), \Theta_{i,r}(\theta'), -2) = (r(\vartheta_i(r', \theta'), -2)), \theta(\vartheta_i(r', \theta', -2)), -2).$$

Also, recall that Hypothesis 12.1, if $R_{i,2}(\theta') = r(\vartheta_i(2, \theta', -2))$ has non-vanishing derivative, except at $\theta'_i$ defined by $\vartheta_i(2, \theta'_i, -2) = (2, \theta_i, -2)$, and that $c_0 > 0$ is the constant defined after the property (44).

For $i = 1, 2$, consider the curves $\gamma_{i,r}(r, \theta, -2)$, defined for $1 \leq r \leq 3$ and $\theta$ such that $(r, \theta, -2) \in D_i$. The transversality assumption on $\sigma_i$ implies that each curve $\gamma_{i,r}$ is non-singular; that is, $\frac{d}{d\theta} \gamma_{i,r}(\theta) \neq 0$. We impose a hypothesis on the shape of these curves for values of the coordinate $r$ near 2, which implies that they have parabolic shape, up to second order.

**HYPOTHESIS 17.2.** For $i = 1, 2$, $2 \leq r_0 \leq 2 + c_0$ and $\theta_i - c_0 \leq \theta \leq \theta_i + c_0$, assume that

$$\frac{d}{d\theta} \Theta_{i,r_0}(\theta) > 0, \quad \frac{d^2}{d\theta^2} R_{i,r_0}(\theta) > 0, \quad \frac{d}{d\theta} R_{i,r_0}(\theta'_i) = 0$$

where $\theta'_i$ satisfies $\vartheta_i(2, \theta'_i, -2) = (2, \theta_i, -2)$. Thus for $2 \leq r_0 \leq 2 + c_0$, the graph of $R_{i,r_0}(\theta)$ is parabolic with vertex $\theta' = \theta'_i$.

Note that (90) is a consequence of Hypothesis 12.1 when $r_0 = 2$.

**DEFINITION 17.3.** A Kuperberg flow $\Phi_t$ is generic if the construction of $K$ and $K$ satisfies Hypotheses 12.1, 12.2 and 17.2. That is, the singularities for the vanishing of the vertical vector field $W$ are of quadratic type, and the insertion yields a quadratic-type radius function near the special points.

Recall from Proposition 2.1 that for each point $x \in R$ with $-1 < z(x) < 1$, its $W$-orbit is forward asymptotic to the periodic orbit $O_2$ and backward asymptotic to the periodic orbit $O_1$. The periodic orbits intersect $R_0$.
in the points \( \omega_i = O_i \cap R_0 \) for \( i = 1, 2 \). Also, recall from (64) that \( I_0 = \mathcal{R} \cap R_0 = \{(2, \pi, z) \mid -1 \leq z \leq 1\} \) is the line segment in \( R_0 \) between \( \omega_1 \) and \( \omega_2 \). Recall that the action of the generator \( \psi \in G_K^* \) defined by the Wilson flow preserves \( I_0 \), and for \( \xi \in I_0 \) with \(-1 < z(\xi) < 1\) we have \( z(\xi) < z(\psi(\xi)) \). Then set
\[
I_\xi = \{(2, \pi, z) \mid z(\xi) < z \leq z(\psi(\xi))\}.
\]

**Lemma 17.4.** Let \( \xi \in I_0 \) with \(-1 < z(\xi) < z(\psi(\xi)) < 0 \) and suppose that \( I_\xi \subset \Sigma \), then \( \Sigma = \mathcal{M} \).

**Proof.** The hypotheses imply that \( I_\xi \) is a fundamental domain for the \( \Psi_t \)-flow on the interior of \( \mathcal{R} \). That is, the \( \mathcal{W} \)-orbit of each interior point \( x \in \mathcal{R} \) intersects the interval \( I_\xi \). If \( I_\xi \subset \Sigma \) then \( \mathcal{R}' \subset \Sigma \), and hence \( \mathcal{M}_0 \subset \Sigma \). As \( \mathcal{M}_0 \) is dense in \( \mathcal{M} \), the conclusion follows.

The strategy of the proof of Theorem 17.1 is to show that for some \( \xi \in I_0 \) sufficiently close to \( \omega_1 \), the \( \mathcal{K} \)-orbit of \( \omega_1 \) contains \( I_\xi \) in its closure. To this end, we establish some estimates on the orbit under \( G_K^* \) of \( \xi \in R_0 \) with \( 2 \leq r(\xi) < 2 + \delta \) where \( \delta > 0 \) is sufficiently small.

We first obtain estimates for the metric behavior of the orbits of the Wilson generator \( \psi \in G_K^* \). Recall the functions \( f \) and \( g \) chosen in Section 2 which are constant in the coordinate \( \theta \), with
\[
W = g(r, \theta, z) \frac{\partial}{\partial z} + f(r, \theta, z) \frac{\partial}{\partial \theta}.
\]

Hypothesis 12.2 and condition 44 imply there exist constants \( A_g, B_g, C_g \) such that the quadratic form \( Q_g(u, v) = A_g \cdot u^2 + 2B_g \cdot u v + C_g \cdot v^2 \) defined by the Hessian of \( g \) at \( \omega_1 \) is positive definite. As a consequence, for \( Q_0(r, z) = (r - 2)^2 + (z + 1)^2 \), there exists \( D_g > 0 \) such that
\[
|g(r, \theta, z) - Q_g(r - 2, z + 1)| \leq D_g \cdot (|r - 2|^2 + |z + 1|^2) \quad \text{for} \quad Q_0(r, z) \leq \epsilon_0^2
\]
\[
\text{where} \; \epsilon_0 \text{is the constant defined in (44). The condition (93) implies that for} \; (r, z) \text{ sufficiently close to} \; (2, -1), \text{the error term on the right-hand-side can be made arbitrarily small relative to the distance squared} \; Q_0(r, z) \text{from the special point} \; (2, -1). \text{We also observe that (93) implies there exist constants} \; 0 < \lambda_1 \leq \lambda_2 \text{ such that}
\]
\[
\lambda_1 \cdot Q_0(r, z) \leq g(r, \theta, z) \leq \lambda_2 \cdot Q_0(r, z) \quad \text{for} \quad Q_0(r, z) \leq \epsilon_0^2.
\]

Next, consider the action of the maps \( \psi^\ell \) for \( \ell > 0 \). Let \( \xi \in R_0 \) with \( 2 \leq r(\xi) \leq 2 + \epsilon_0 \) and \(-7/4 \leq z(\xi) \leq -1/4 \), such that \( \psi(\xi) \) is defined and \( z(\psi(\xi)) < 0 \). Let \( T(\xi) > 0 \) be defined by \( \psi(\xi) = \Psi_{T(\xi)}(\xi) \). Then the \( z \)-coordinate of \( \psi(\xi) \) is given by
\[
z(\psi(\xi)) - z(\xi) = \int_0^{T(\xi)} g(\Psi_s(\xi)) \, ds \geq 0.
\]
If \( \xi \neq \omega_1 \) then \( g(\Psi_s(\xi)) \) is positive along the orbit segment for \( 0 \leq s \leq T(\xi) \), hence \( z(\psi(\xi)) - z(\xi) > 0 \).

Note that if the orbit of \( x \in \mathcal{W} \) avoids the \( \epsilon_0 \)-tube around the periodic orbits \( O_i \), then \( g \equiv 1 \) along the orbit, so the \( z \)-coordinate along the orbit increases at constant rate \( 1 \). As the cylinder \( \mathcal{C} \) has height 4, this means that such an orbit traverses an angle of at most 4\( \pi \), hence it does not complete a full turn around the cylinder \( \mathcal{C} \). In particular, for \( \xi \in R_0 \) with \( r(\xi) \geq 2 + \epsilon_0 \) and \( z(\xi) < 0 \) with \( \psi \) defined at \( \xi \), this implies the \( \mathcal{W} \)-orbit crosses the annulus \( \mathcal{A} \) where \( z = 0 \), then returns to intercept \( R_0 \) with \( z(\psi(\xi)) > 0 \). On the other hand, for \( \xi \in R_0 \) with \( 2 < r(\xi) < 2 + \delta \) for \( \delta \ll \epsilon_0 \) and \( z(\xi) < -1 \), the \( \mathcal{W} \)-orbit traverses a region near \( O_1 \) where the slope is close to 0, and hence repeatedly traverses the rectangle, with the number of revolutions increasing as \( \delta \to 0 \). In particular, for such \( \xi \), the powers \( \psi^\ell(\xi) \) form a sequence of points in the vertical line \( r = r(\xi) \) with increasing \( z \)-coordinates, as has been noted previously, especially in the proofs of Propositions 7.5 and 7.6.

We next combine (93) with (95) to obtain metric estimates on the orbit of \( \omega_1 \) under the action of \( G_K^* \). Recall that the first transition point for the forward orbit of \( \omega_1 \) is the special entry point \( p_1 = r(L_1 \cap O_1) \) with \( r(p_1) = 2 \), as illustrated in Figure 16. Section 12 introduced the alternate notation \( p'(1) = p_1^{-1} \in E_1 \) and \( p(1) = r^{-1}(p'(1)) \in L_1 \), where \( r(p(1)) = 2 \) by the Radius Inequality.

The forward \( \mathcal{W} \)-orbit of \( p(1) \) is trapped in the region \( \mathcal{C} \cap \{ z < -1 \} \), and thus intercepts \( L_1 \cap \mathcal{C} \) in an infinite sequence of points with increasing \( z \)-coordinates between \(-2 \) and \(-1 \). For all \( \ell \geq b \), these points
are labeled $p'(1;1,\ell) \in \mathcal{L}_1^-$, where $r(p'(1;1,\ell)) = 2$ and $z(p'(1;1,\ell)) < z(p'(1;1,\ell+1)) < -1$. Moreover, $z(p'(1;1,\ell)) \to -1$ as $\ell \to \infty$.

For each $\ell \geq 0$, set $p(1;1,\ell) = \sigma_1^{-1}(p'(1;1,\ell)) \in \mathcal{L}_1^-$ then $r(p(1;1,\ell)) > 2$. Note that $r(p(1;1,\ell)) \to 2$ as $\ell \to \infty$, and the sequence $p(1;1,\ell)$ accumulates on $p(1)$ in $L_1^-$.

Recall from Section 13 that corresponding to the sequence $\{p'(1;1,\ell) \mid \ell \geq 0\} \subset \mathcal{L}_1^-$ is a sequence $\{p_0(1;1,\ell) \mid \ell \geq 0\} \subset \mathbf{R}_0$ where $p_0(1;1,\ell)$ is the point in $\mathbf{R}_0$ whose forward $W$-orbit has $p'(1;1,\ell)$ as its first transition point. Thus, $r(p_0(1;1,\ell)) = 2$, and $p_0(1;1,\ell+1) = \psi(p_0(1;1,\ell))$ for $\ell \geq 1$, with $z(p_0(1;1,\ell)) \to -1$ (see Figure 46). Define $0 < t_1 < t_2 < \cdots$ such that $\Psi_{t_\ell}(p_0(1;1,0)) = p_0(1;1,\ell)$.

![Figure 46. Iterations of $\Gamma_0$ and $\Lambda_0$ in $\mathbf{R}_0$ under $G_K^*$](image)

**LEMMA 17.5.** There exists constants $C_2, C_3 > 0$ such that for all $\ell \geq \ell_0$, where $\ell_0 > 0$ is such that $z(p_0(1;1,\ell_0)) > -(1 + \epsilon_0)$, then we have:

\[
\frac{-1}{4\pi \lambda_1 \ell + C_2} < z(p_0(1;1,\ell+1)) + 1 < \frac{-1}{4\pi \lambda_2 \ell + C_3}.
\]

Moreover, for the constants $\lambda_1 \leq \lambda_2$ introduced in [94], there exists constants $C_4, C_5, C_6 > 0$ such that for all $\ell \geq \ell_0$,

\[
\frac{C_4}{(4\pi \lambda_1 \ell)^2 + C_5} \leq z(p_0(1;1,\ell+1)) - z(p_0(1;1,\ell)) \leq \frac{C_4}{(4\pi \lambda_2 \ell)^2 + C_6}.
\]

**Proof.** Note that $z(p_0(1;1,\ell_0)) > -(1 + \epsilon_0)$ implies the $W$-orbit of $p_0(1;1,\ell_0)$ satisfies

$-(1 + \epsilon_0) < z(\Psi_t(p_0(1;1,\ell_0))) < -1$ for all $t \geq 0$,

and thus $f(\Psi_t(p_0(1;1,\ell_0))) = 1$. It then follows from (92) that $t_\ell = t_{\ell_0} + 4\pi (\ell - \ell_0)$ for all $\ell \geq \ell_0$.

Set $z(t) = z(\Psi_t(p_0(1;1,\ell_0)))$ for $t \geq 0$, so that $-(1 + \epsilon_0) < z_0 = z(p_0(1;1,\ell_0)) < -1$. Then we have

\[
\lambda_1 \cdot (1 + z(t))^2 \leq \frac{dz}{dt} \leq \lambda_2 \cdot (1 + z(t))^2.
\]

As $z(0) = z_0$ set $C_1 = -1/(z_0 + 1) > 0$ then we have

\[
\frac{-1}{\lambda_1 t + C_1} \leq z(t) + 1 \leq \frac{-1}{\lambda_2 t + C_1}.
\]

Substitute $t_\ell = t_{\ell_0} + 4\pi (\ell - \ell_0)$ into (99) and collect constants to obtain (96).
The estimate \[ (97) \] follows by subtracting terms in \( (96) \) for \( \ell \) and \( \ell + 1 \), and gathering constants. Alternately, one can use the formula \( (94) \) and the estimate \( (93) \) to obtain \( (97) \). \( \square \)

The estimates in Lemma 17.5 have counterparts for \( \xi \in I_0 \) with \(-1 < z(\xi) < 0\) for which \( z(\psi(\xi)) < -1 + \epsilon_0 \).

In particular, the length of the interval \( I_\xi \) defined in \( (91) \) has quadratic upper and lower bound estimates as a function of \( |z(\xi)| + 1\).

We next obtain a more precise estimate than \( (93) \) for the restriction of \( g(2, \theta_0, z) \) to the line \( I_0 \).

Note that for some \( \lambda_1 \leq \lambda_g \leq \lambda_2 \), the Taylor expansion for \( g(2, \theta_0, z) \) gives the approximation \( g(2, \theta_0, z) = \lambda_g (z + 1)^2 + O(|z + 1|^3) \). Next, choose a scale \( 0 < \epsilon_3 < \epsilon_0 / 2 \) sufficiently small so that this approximation is strong enough to control the dynamics of the \( \Psi_\ell \)-flow near the cylinder \( C \).

**Definition 17.6.** Let \( 0 < \epsilon_3 \leq \min \{ \epsilon_0 / 2, 1 / 100, 1 / (300 \lambda_g) \} \) be such that
\[
|g(2, \theta_0, z) - \lambda_g (z + 1)^2| \leq \frac{\lambda_g (z + 1)^2}{100} \quad \text{for } |z + 1| \leq \epsilon_3.
\]

As a consequence, we have
\[
.99 \cdot \lambda_g (z + 1)^2 \leq g(2, \theta_0, z) \leq 1.01 \cdot \lambda_g (z + 1)^2 \quad \text{for } |z + 1| \leq \epsilon_3.
\]

A key point is that we can now choose a \( \delta_3 > 0 \) so that a weaker form of the estimate \( (101) \) holds for some neighborhood of a fundamental domain \( I_\xi \) in \( I_0 \) as defined by \( (91) \). Let \( 0 < \delta_3 < \epsilon_0 / 2 \) be such that the following two estimates hold:
\[
|r - 2| \leq \delta_3 \text{ and } |z + 1| \leq \epsilon_3 \implies 0 \leq g(r, \theta_0, z) \leq 1.02 \cdot \lambda_g(\epsilon_3)^2.
\]
\[
|r - 2| \leq \delta_3 \text{ and } \epsilon_3 / 4 \leq z + 1 \leq \epsilon_3 \implies .98 \cdot \lambda_g(\epsilon_3)^2 \leq g(r, \theta_0, z) \leq 1.02 \cdot \lambda_g(\epsilon_3)^2.
\]

Note that the assumption that \( g \) is non-degenerate in Hypothesis 12.2 and the estimate \( (94) \) implies that for \( \epsilon_3 \) sufficiently small, there exists a constant \( C_g > 0 \) such that \( \delta_3 = \epsilon_3 / C_g \).

We next introduce the “target box”, which is key to the proof of Theorem 17.1.
\[
R_0(\delta_3, \epsilon_3) = \{(r, z) \in R_0 | |r - 2| \leq \delta_3, \epsilon_3 / 4 \leq z + 1 \leq \epsilon_3\}.
\]

**Definition 17.7.** We say that \( \xi \in R_0 \) and \( \ell > 0 \) satisfy Condition \( R(\delta_3, \epsilon_3, \ell) \) if
\[
z(\xi) < -1, \quad 2 < r(\xi) \leq 2 + \delta_3
\]
\[
\epsilon_3 / 3 < z(\psi^\ell(\xi)) + 1 < z(\psi^{\ell+1}(\xi)) + 1 < \epsilon_3 / 2.
\]

We then have an analog for \( r > 2 \) of Proposition 7.3.

**Lemma 17.8.** For \( \delta_3, \epsilon_3 \) as above and \( \xi \in R_0 \) satisfying \( (105) \), there exists \( \ell > 0 \) such that \( (106) \) is satisfied.

**Proof.** As \( z(\xi) < -1 \) is assumed, there is a unique \( t_1 > 0 \) so that \( z(\Psi_{t_1}(\xi)) = -1 + \epsilon_3 / 4 \), and let \( t_2 \geq t_1 \) be the first subsequent time for which \( \Psi_{t_2}(\xi) \in R_0 \). Note that \( t_2 - t_1 \leq 2 \pi r(\xi) < 6 \pi \), and so by \( (95) \) and \( (102) \) and Definition 17.6 we obtain
\[
z(\Psi_{t_2}(\xi)) - z(\Psi_{t_1}(\xi)) \leq 6 \pi \cdot 1.02 \cdot \lambda_g(\epsilon_3)^2 \leq \epsilon_3 \cdot 20 / 300 = \epsilon_3 / 15 < \epsilon_3 / 12
\]
so that \( z(\Psi_{t_2}(\xi)) + 1 < \epsilon_3 / 3 \). The same estimates as in \( (107) \) show that
\[
z(\psi^{\ell+1}(\Psi_{t_2}(\xi))) - z(\psi^\ell(\Psi_{t_2}(\xi))) \leq \epsilon_3 / 15 < \epsilon_3 / 12
\]
for all \( \ell > 0 \) for which \( z(\psi^\ell(\Psi_{t_2}(\xi))) + 1 < \epsilon_3 / 2 \). The estimate \( (106) \) then follows. \( \square \)
The slope of $W$ for COROLLARY 17.10. Let 
\begin{equation}
|z| < 0, \text{ set } y_1 = \Psi(t_1), \text{ then }
\end{equation}
Then by the Mean Value Theorem, we have: 
Proof. Let $s_1$ be defined by 
\begin{equation}
z(\Psi_s(x'_1)) = z(x_1). \text{ As the slope of the vector field } W \text{ near } x_1 \text{ is } g(x_1)/f(x_1) = 1, \text{ we have } s_1 = -\Delta z, \text{ and hence } \theta(\Psi_s(x'_1)) = \theta_1 - \Delta z. \text{ Thus, } x_1 = R_s(\Psi(x'_1)) \text{ and so }
\end{equation}
\begin{equation}
z(\Psi_t(x'_1)) = z(\Psi_t(\Psi_s(x'_1))) = z(R_s(\Psi_s(x'_1))) = z(\Psi_s(y_1))
\end{equation}
The slope of $W$ at $y_1$ is $f(y_1)$ as $f(y_1) = 1$, so that $z(\Psi_s(y_1)) = z(y_1) + g(y_1) \cdot \Delta z$, which yields (108). 

In the case where $x_1 = \xi \in \mathbb{R}_0$ and $\Psi_t$ is the map defining $\psi^t$, then the estimate (108) can be made precise. For $t \geq 0$, set $\xi_t = \psi^t(\xi)$. Define $T(\xi_0, t) > 0$ by $\psi^t(\xi) = \Psi_t(\xi_0)$. 

COROLLARY 17.10. Let $\xi_0 \in \mathbb{R}_0$ with $-7/4 \leq z(\xi_0) \leq -1 - \epsilon_0$ and $\ell > 0$ satisfy Condition $R(\delta_3, \epsilon_3, \ell)$. Then for $\Delta z$ sufficiently small so that $\xi_0 = \xi_0 + \Delta z$ again satisfies Condition $R(\delta_3, \epsilon_3, \ell)$, we have 
\begin{equation}
|z(\psi^t(\xi_0)) - z(\psi^t(\xi_0))| \leq 1.02 \cdot \lambda_3(\epsilon_3)^2 \cdot \Delta z
\end{equation}
Proof. The point $\xi_0$ satisfies the conditions of Lemma 17.9 and then use (103) in the proof. 

We next develop an estimate for $z(\psi^t(\xi_0)) - z(\psi^t(\xi_0))$, where $\xi_0 = \xi_0 + \Delta r$. Assume that $\xi_0 \in \mathbb{R}_0$ with $-7/4 \leq z(\xi_0) \leq -1 - \epsilon_0$ and $\ell > 0$ satisfy condition $R(\delta_3, \epsilon_3, \ell)$. Also assume that $\Delta r$ is sufficiently small so that $\xi_0 = \xi_0 + \Delta r$ again satisfies condition $R(\delta_3, \epsilon_3, \ell)$. 

Then the $z$-coordinate $z(\Psi_t(\xi_0))$ increases at constant rate 1 in the region $\{z \leq -1 - \epsilon_0\}$, and subsequently increases at a possibly slower rate in the region $\{-1 - \epsilon_0 < z < -1 + \epsilon_0\}$. The $W$-orbit segment $\{\Psi_t(\xi_0) | 0 \leq t \leq T(\xi_0, \ell)\}$ is geometrically a “coiled spring” in $W$ which wraps $\ell$-times around the cylinder $\{r = r(\xi)\}$, with the coils most “tightly spaced” near the periodic orbit $\mathcal{O}_1$. If $\Delta r > 0$ then the orbit $\{\Psi_t(\xi_0) | 0 \leq t \leq T(\xi_0', \ell)\}$ is slightly less tightly spaced, so the ends of the orbit segment are spaced further apart. More precisely, we have 
\begin{equation}
z(\psi^t(\xi_0)) = z(\xi_0) + \int_0^{\ell(\xi_0, \ell)} g(\Psi_s(\xi_0)) \, ds
\end{equation}
Obtaining a sharp estimate for $z(\psi^t(\xi_0)) - z(\psi^t(\xi_0))$ requires estimating this integral as $\Delta r$ varies in the expression $r(\xi_0') = r(\xi_0) + \Delta r$, and this requires more detailed estimates of the integrand $g(\Psi_s(\xi_0))$ than is given. However, a sufficient estimate can be obtained by noting that $z(\psi^t(\xi_0))$ is a smooth function with bounded derivatives on any compact set $K \subset \mathbb{R}_0$ contained in the domain of $\psi^t$. For $0 < \delta_4 < \delta_3$, define: 
\begin{equation}
K(\epsilon_3, \delta_3, \delta_4) = \{(r, z) | -2 \leq z \leq -1 - \epsilon_3 \text{ and } 2 + \delta_4 \leq r \leq 2 + \delta_3\}
\end{equation}
which is a compact set contained in the domain of $\psi^t$. Then for the function $g$ chosen, define: 
\begin{equation}
M(g, \ell, \epsilon_3, \delta_3, \delta_4) = \max \left\{ \frac{\partial z(\psi^t(r, z))}{\partial r} \mid (r, z) \in K(\epsilon_3, \delta_3, \delta_4) \right\}
\end{equation}
Then by the Mean Value Theorem, we have: 

LEMMA 17.11. Let $\xi_0 \in \mathbb{R}_0$ and $\Delta r$ be such that $\xi_0, \xi_0' \in K(\epsilon_3, \delta_3, \delta_4)$, where $\xi_0' = \xi_0 + \Delta r$. Then 
\begin{equation}
|z(\psi^t(\xi_0)) - z(\psi^t(\xi_0))| \leq M(g, \ell, \epsilon_3, \delta_3, \delta_4) \cdot \Delta r
\end{equation}
The idea of the proof of Theorem 17.1 is to show that for \( \epsilon_3 > 0 \) as in Definition 17.6 and for any \( \delta_3 \) satisfying (102) and (103), the orbits of \( \omega_1 \) under \( G^*_K \) yields a set of points which have dense \( z \)-coordinates in a rectangle defined by (102). As \( \delta_3 \) can be chosen arbitrarily small, this implies that the closure of the orbit of \( \omega_1 \) contains a fundamental domain for the \( \Psi_r \)-flow on \( R \) as in (61), so the claim that \( \Sigma = \mathbb{M} \) follows from Lemma 17.4. The derivations of the estimates used in the proof of these statements depend fundamentally on Hypothesis 17.2.

The \( K \)-orbit of \( \omega_1 \in R_0 \) defines the sequence of points \( \{p'(1;1,\ell) \mid \ell \geq 0\} \subseteq \mathcal{L}^-_\ell \) for \( \ell \geq 0 \), and corresponding points \( \{p_0(1;1,\ell) \mid \ell \geq 0\} \subseteq R_0 \) with \( r(p_0(1;1,\ell)) = 2 \) and \( z(p_0(1;1,\ell)) \to -1 \), where the convergence of \( z(p_0(1;1,\ell)) \) is estimated by Lemma 17.5.

Assume that \( a = b = 0 \) for \( a \) and \( b \) as defined in Sections 13 and 12 respectively. For each \( \ell \geq 0 \), we then have the curve \( \kappa_0(\ell) \subseteq R_0 \) with lower endpoint \( p_0(1;1,\ell) \). For \( \ell = 0 \), the lower part of the curve \( \kappa_0(0) \) is the image of the segment \( J_0 \subseteq R_0 \) under the map \( \phi^+_1 \subseteq G^*_K \), and \( \kappa_0(\ell) \) is the image of \( \kappa_0(0) \) under the map \( \psi^\ell \) for \( \ell \geq 0 \).

The curve \( \kappa_0(0) \) is “parabolic” by Hypothesis 17.2. That is, the \( r \)-coordinate of the graph is approximated by a quadratic function of the \( z \)-coordinate, for \( z \) near \( p_0(1;1,0) \). In particular, the \( r \)-value of points on \( \kappa_0(0) \) increases as \( -(1+z) \) increases for \( z \leq -1 \). As the map \( \psi \) preserves the radius coordinate, the same monotonicity property is true for each of the curves \( \kappa_0(\ell) \), as illustrated in the graphs in Figure 32.

Note that the image under the map \( \phi^+_1 \) of the points \( \{p_0(1;1,\ell) \mid \ell \geq 0\} \) yields a sequence of points \( p_0(1;1,\ell;1,0) \subseteq \kappa_0(0) \) for which \( r(p_0(1;1,\ell;1,0)) > 2 \) and \( p_0(1;1,\ell;1,0) \to p_0(1;1,0) \) as \( \ell \to \infty \). Thus \( r(p_0(1;1,\ell;1,0)) \to 2 \) as \( \ell \to \infty \).

Choose \( m_1 > 0 \) such that \( r(p_0(1;1,m_1;1,0)) < 2 + \delta_3 \). By Lemma 17.8 there exists \( \ell_1 > 0 \) such that
\[
\epsilon_3/3 < z(p_0(1;1,m_1;1,\ell_1)) + 1 < z(p_0(1;1,m_1;1,\ell_1)) + 1 < \epsilon_3/2,
\]

since \( p_0(1;1,m_1;1,\ell_1) = \psi^{\ell_1}(p_0(1;1,m_1;1,0)) \).

Choose \( n_1 > m_1 \) such that \( r(p_0(1;1,n_1;1,0)) \leq r(p_0(1;1,m_1;1,\ell_1)) \), and set \( \delta_4 = r(p_0(1;1,n_1;1,0)) - 2 \).

Observe that the \( r \)-coordinate along the curve \( \kappa_0(0) \) between \( p_0(1;1,n_1;1,0) \) and \( p_0(1;1,m_1;1,0) \) is monotone increasing by Hypothesis 17.2 hence have \( r \) values ranging between \( 2 + \delta_4 \) and \( 2 + \delta_3 \). We next select a collection of sequences of points in the \( G^*_K \)-orbit of \( \omega_1 \) which are sufficiently closely spaced, and which “shadow” this curve segment. Applying the map \( \psi^{\ell_1} \) will then yield a collection of points in the region \( R_0(\delta_3,\epsilon_3) \) which have arbitrarily dense \( z \)-coordinates.

Introduce the constant
\[
\mu = 2 \cdot \max \{ M(g,\ell_1,\epsilon_3,\delta_3,\delta_4) , 1.02 \cdot \lambda_3(\epsilon_3)^2 \}
\]
where \( M(g,\ell_1,\epsilon_3,\delta_3,\delta_4) \) is defined by 113 and the second term is introduced in 110. Then \( \mu > 2 \), and for \( N \geq 2 \), set
\[
\epsilon_N = \frac{z(p_0(1;1,m_1;1,\ell_1+1)) - z(p_0(1;1,m_1;1,\ell_1))}{N} < 1/8, \quad \delta_N = \epsilon_N/\mu.
\]

The image under \( \phi^+_1 \) of the lower part of the parabolic curve \( \kappa_0(n_1) \) with lower endpoint \( p_0(1;1,n_1) \) is part of the curve \( \kappa_0(1,n_1;0) \) with lower endpoint \( p_0(1;1,n_1;1,0) \). Thus, the lower part of \( \kappa_0(1,n_1;0) \) is the image of the interval \( J_0 \) under the composition \( \phi^+_1 \circ \psi^{n_1} \circ \phi^+_1 \). Applying this map to the sequence \( p_0(1;1,\ell) = \psi^\ell(p_0(1;1,0)) \) yields a collection of points on the curve \( \kappa_0(1,n_1;0) \) which converge to \( p_0(1;1,n_1;1,0) \), as in Figure 17. By Lemma 17.5 there exists \( n_2 > 0 \) so that for the collection
\[
O(\delta_N;n_1,n_2) = \{ \phi^+_1 \circ \psi^{n_1} \circ \phi^+_1 \circ \psi^\ell(p_0(1;1,0)) \mid \ell \geq n_2 \} \subseteq \kappa_0(1,n_1;0),
\]
the differences of both the \( z \) and \( r \)-values of successive points for \( \ell, \ell+1 \geq n_2 \) are bounded above by \( \delta_N \).

By making \( n_2 \) bigger, we can assume that the point \( p_0(1;1,n_2;1,n_1;1,0) \) has the largest \( r \)-coordinate for all points in \( O(\delta_N;n_1,n_2) \).
We now proceed inductively. Assume that the integers \(\{n_1, n_2, \ldots, n_k\}\) have been chosen, with associated sets \(O(\delta_N; n_1, n_2, \ldots, n_k) \subset \mathcal{G}_K(\omega_1)\) for \(i \leq k\), so that \(p_0(1; 1, n_1, n_1-1; \ldots; 1, n_1; 1, 0)\) satisfies that

\[
r(p_0(1; 1, n_1, n_1-1; \ldots; 1, n_1; 1, 0))
\]

is the maximum of the \(r\)-values for all points in \(O(\delta_N; n_1, n_2, \ldots, n_k)\).

Suppose that \(r(p_0(1; 1, n_k; 1, n_k-1; \ldots; 1, n_1; 1, 0)) < r(p_0(1; 1, m_1; 1, 0))\), then the previous points chosen lie inside the region defined by the region bounded by the parabola \(\Gamma_0(1, n_1; 0)\) and the region \(\{r \leq r(p_0(1; 1, m_1; 1, 0))\}\) which lies inside the \(\epsilon_0\)-ball in \(\mathbb{R}_0\) about \(\omega_1\). Thus, we can continue the above process, and choose \(n_{k+1}\) as follows. The curve \(\kappa_0(1, n_k; 1, n_k-1; \ldots; 1, n_1; 0)\) with lower endpoint \(p_0(1; 1, n_k; 1, n_k-1; \ldots; 1, 0)\) is the image of \(J_0\) under the composition of maps

\[
\phi_1^+ \circ \psi_1 \circ \phi_1^+ \circ \psi_2 \circ \phi_1 \circ \cdots \circ \psi_{n_k} \circ \phi_1^+
\]

Thus, applying the map in (119) to the sequence \(\{p_0(1; 1, \ell) \mid \ell \geq 0\}\) yields a collection of points on the curve \(\kappa_0(1, n_k; \ldots; 1, n_1; 0)\) which converge to \(p_0(1; 1, n_k; 1, n_k-1; \cdots; 1, 0)\). Then by Lemma [17.5] there exists \(n_{k+1} > 0\) so that for the collection

\[
O(\delta_N; n_1, n_2, \ldots, n_{k+1}) = \{\phi_1^+ \circ \psi_1 \circ \phi_1^+ \circ \psi_2 \circ \phi_1 \circ \cdots \circ \psi_{n_k} \circ \phi_1^+(p_0(1; 1, \ell)) \mid \ell \geq n_{k+1}\}
\]

which is contained in the curve \(\kappa_0(1, n_k; \ldots; 1, n_1; 0)\), the differences of both the \(z\) and \(r\)-values of successive points for \(\ell, \ell + 1 \geq n_{k+1}\) are bounded above by \(\delta_N\). We can assume that \(r(p_0(1; 1, n_{k+1}; 1, n_k; \cdots; 1, n_1; 0))\) is the maximum of the \(r\)-values for all points in \(O(\delta_N; n_1, n_2, \ldots, n_{k+1})\).

The collections of points defined by (120) are contained in the region bounded by the parabola \(\Gamma_0(1, n_1; 0)\). Hypothesis [17.2] implies the composite functions in (119) have non-zero derivatives which are bounded away from zero for points in the region \(\delta_4 \leq r(\xi) \leq \delta_5\) and \(z(\xi) \leq -1 - \epsilon_0\). If \(r(p_0(1; 1, n_{k+1}; 1, n_k; \cdots; 1, n_1; 0) < r(p_0(1; 1, m_1; 1, 0))\) then the \(\kappa_0\) curve with lower endpoint at \(p_0(1; 1, n_{k+1}; 1, n_k; \cdots; 1, n_1; 0)\) is defined, and so we can repeat the process to increase \(r(p_0(1; 1, n_{k+1}; 1, n_k; \cdots; 1, n_1; 0))\), unless \(r(p_0(1; 1, n_{k+1}; 1, n_k; \cdots; 1, n_1; 0)) \geq r(p_0(1; 1, m_1; 1, 0))\), in which case the inductive selection of points terminates.

Now apply the map \(\psi^{\xi}\) to each of the sets \(O(\delta_N; n_1, n_2, \ldots, n_k)\) to obtain points in the region \(R_0(\delta_3, \epsilon_3)\). Then Corollary [17.10] and Lemma [17.11] imply the difference of the \(z\)-values of successive points in the sequence
are bounded above by $\mu \cdot \delta_N = \epsilon_N$. Finally, by construction the upper $r$-value of points in $O(\delta_N; n_1, n_2, \ldots, n_k)$ is approached by the descending $r$-values of points in $O(\delta_N; n_1, n_2, \ldots, n_{k+1})$.

Thus, the image of $G^*_K(\omega_1)$ contains points which are in the strip $2 < r \leq 2 + \delta_2$ and whose $z$-values increase from $z(p_0(1; 1, m_1; 1, \ell_1))$ to $z(p_0(1; 1, m_1; 1, \ell_1 + 1))$ in increments at most $\epsilon_N$. As $\delta_3 > 0$ and $N \gg 0$ were arbitrary, this implies the closure of $G^*_K(\omega_1)$ contains $R$, as was to be shown to establish Theorem 17.1. □

We conclude with a remark on the proof of Theorem 17.1: The quadratic assumption in Hypothesis 12.2 was not used in any essential way, except to obtain precise estimates on the spacing of the orbits of $W$. It seems like that a much weaker assumption than this hypothesis should suffice for the proof.

18. Geometry of curves in $R_0$

The aim of this section is to investigate the geometry of the collection of curves formed by the intersection $\mathcal{M}_0 \cap R_0$, thus of $\gamma_0$ and $\lambda_0$ curves. Up to now, we have only used their topology and the fact that the $\Gamma_0$ and $\Lambda_0$ curves form families of nested ellipses in $R_0$. For a generic Kuperberg flow, as defined by Definition 17.3, we obtain estimates on the geometry of these curves, including the following result which has applications in Sections 19 and 22.

THEOREM 18.1. Let $\Phi$ be a generic Kuperberg flow on $K$. Then there exists $L > 0$ such that each connected component of $\mathcal{M}_0 \cap R_0$ is a curve with length bounded above by $L$.

For $\gamma_0$ and $\lambda_0$ curves of level 1, the $r$-coordinate along the lower half of the curve is monotone increasing. If such condition was true for any curve in $\mathcal{M}_0 \cap R_0$, the theorem will be trivial. As we explain below this monotonicity condition does not holds for curves at level 2 or higher. To describe how $\gamma_0$ and $\lambda_0$ curves fold, we introduce a new set of curves, the $\Lambda_0$-curves.

For simplicity, we will restrict our discussion to $\gamma_0$ curves. Recall that the union of $\gamma_0$ and $\kappa_0$ curves gives $\Gamma_0$ curves, that at high levels are very thin (as a consequence of the nesting property). Hence the shape of a $\Gamma_0$ curve, that is a closed curve, can be seen as the shape of a simple curve. These are the $A_0$-curves described below.

As mentioned above, the lower half of a $\gamma_0$ curve of level at least 2 has no monotone radius. Then, the curve in $E_1$ generating the corresponding propeller has no monotone radius which implies that the propeller can have internal notches that do not correspond to the ones introduced in Section 12. These new internal notches generate also compact surfaces, to which we refer as bubbles of second type (the bubbles of first type being the ones introduced in Section 15). This phenomena is discussed at the end of this section.

The two aspects we are interested in are the following. First, we show that the lengths of $\gamma_0$ and $\lambda_0$ curves having one endpoint in the domain of $\phi_1^+$ and the other endpoint in the domain of $\phi_2^+$ has an upper bound. Observe that such curves admit $2 - 2\epsilon_0$ as a trivial lower bound. Second, these curves are “nice flat” arcs away from their endpoints, in the sense that if we consider a propeller generated by a $\gamma$-curve truncated near its tip, the trace that we obtain on the annulus $A = \{z = 0\}$ will be a spiral that is never tangent to the lines $\{\theta = \text{const}\}$.

To prove Theorem 18.1 let us start by analyzing level 1 curves. Recall that the curves $\Gamma_0(\ell)$ for $\ell \geq a$ and unbounded, form the trace of the propeller $\tau(P_0^\ell)$ on $R_0$. Hypothesis 12.1 implies that $\Gamma \subset L_1^\ell$ is a parabolic curve with vertex at $p(1) = \sigma_1^{-1}(p_1^\ell)$ as illustrated in Figure 29. Thus the curves $\Gamma_0(\ell)$ are tangent to the vertical line $r = 2$ at two points, their vertices, with parabolic shape near these points, as in Figure 31.

The points in $\Gamma_0(\ell) \subset W$ belong to Wilson orbits that intersect at least $a + \ell$ times $R_0$, thus orbits that turn at least $a + \ell - 1$ times around the cylinder $C$ before hitting $A$. It follows that the radius coordinate along these curves, for $\ell > a$, is bounded above by $2 + \epsilon_0$. Thus the curves are contained in the rectangle $[2, 2 + \epsilon_0] \times [-2, 2]$. Moreover, outside the $\epsilon_0$ tube around the periodic orbits $O_i$, for $i = 1, 2$, we have that $g = 1$ and thus a Wilson orbit intersects at most twice $R_0$ in this region, once in each direction. Hence the
curves $\Gamma_0(\ell)$ are almost vertical outside the $\epsilon_0$-neighborhood of the points $\omega_i$. These considerations apply to higher level $\Gamma_0$-curves.

The problem of describing higher level $\Gamma_0$ curves comes from the fact that the curves $\Gamma(i, \ell) \subset L^-_i$ for $i = 1, 2$ do not have monotone radius along $\gamma(i, \ell)$ and the same might apply to the curves $\kappa(i, \ell)$. To illustrate this situation, let us consider the curve $\Gamma_0(\ell)$ for $\ell \geq 0$. The hypothesis $\ell \geq 0$ implies that the positive orbit of its points hit $E_1$ along $\tau(\Gamma(1, \ell))$, that is tangent to the vertical line $r = 2$. Thus $\Gamma(1, \ell) \in L^-_1$ is tangent to $\Gamma$ at $p(1; 1, \ell)$ and is composed of the union of $\gamma(1, \ell)$ and $\kappa(1, \ell)$. The circle with radius $r = r(p(1; 1, \ell))$ is transverse to $\gamma$ at two points, one being $p(1; 1, \ell)$. Thus $\gamma(1, \ell)$ can not have monotone radius, as illustrated in Figure 48.

![Intersection of $\Gamma(1, \ell)$ with the circle $r = r(p(1; 1, \ell))$ in $L^-_1$](image)

**Figure 48.** Intersection of $\Gamma(1, \ell)$ with the circle $r = r(p(1; 1, \ell))$ in $L^-_1$

Observe that Hypothesis 17.2 implies that a curve in $L^-_1$ crossing the line $z = -1$ is bended by the inverse of the insertion map $\sigma_1^{-1}$ at the point with $z$-coordinate equal to $-1$. If the original curve is vertical, we obtain a parabolic curve in $L^-_1$. For example, $\Gamma' \subset L^-_1$ is the vertical straight line and becomes the parabolic curve $\Gamma \in L^-_1$ with axis $\sigma_1^{-1}(\{z = -1\})$.

Let $A' = \{z = -1\} \subset L^-_1$, then the curve $A = \sigma_1^{-1}(A') \subset L^-_1$ is a straight line connecting the boundary of $\partial_n \mathbb{W}$ to the point $p(1)$ with radius 2. Observe that $A$ is inside the region of $L^-_1$ that is bounded by $\Gamma$.

The propeller $P_A$ is an infinite propeller as in Definition 1.1. Consider the notched propeller $P'_A = P_A \cap \mathbb{W}'$ and its image $\tau(P'_A)$ in $K$. The trace of this propeller on the rectangle $R_0$ is an infinite family of arcs $A_0(\ell)$, each one of them being in the region of $R_0$ that is bounded by $\Gamma_0(\ell)$, for the same index $\ell$. Since $A$ intersects $\Gamma$ at the special point $p(1) \in L^-_1$, for each $\ell$ the curve $A_0(\ell)$ intersects $\Gamma_0(\ell)$ at the two points $p_0(1; 1, \ell)$ and $p_0(1; 2, \ell)$. Recall that these are the points where $\Gamma_0(\ell)$ is tangent to the vertical line $r = 2$.

From the curve $A \subset L^-_1$ we can construct the infinite family of $A$-curves and the corresponding $A_0$-curves in $R_0$. Observe that a level $n$ curve in the later family is contained in the region of $R_0$ bounded by a $\Gamma_0$-curve at the same level, in fact, by the $\Gamma_0$-curve having exactly the same label. We will say that the $\Gamma_0$-curve *envelops* the $A_0$-curve. To be more precise $\Gamma_0(i_1, \ell_1; \cdots; \ell_n)$ envelops $A_0(i_1, \ell_1; \cdots; \ell_n)$ and these two curves intersect at the points $p_0(1; i_1, \ell_1; \cdots; 1, \ell_n)$ and $p_0(1; i_1, \ell_1; \cdots; 2, \ell_n)$. Finally, observe that at the intersection points the curves are transverse to each other and locally $\Gamma_0(i_1, \ell_1; \cdots; \ell_n)$ has parabolic shape with axis $A_0(i_1, \ell_1; \cdots; \ell_n)$.

As we comment at the beginning of the section we are interested in finding upper bounds to the length of $\gamma_0$-curves and describing the end parts of these curves. The length of such curves is approximated by the length of $A_0$-curves, thus it is enough to find a uniform upper bound to the length of $A_0$-curves.
We consider next $A$-curves in detail. Let $A'(i, \ell) \subset \mathcal{L}_1^\ell$ be the entry curves of the notches of the propeller $P_A'$ and $A(i, \ell) = \sigma_1^{-1}(A'(i, \ell)) \subset \mathcal{L}_1^\ell$, for $i = 1, 2$. Hypothesis [12.2] on the Wilson flow, implies that for $r > 2 + \epsilon_0$ the vertical component of the vector field is equal to 1 and thus the lines $A_0(\ell)$ are steep in this region. Then there exists some positive number $B$ such that for $\ell \geq B$ the curve $A'(1, \ell)$ intersects transversally $A'$. Let $q'(1; 1, \ell)$ be the intersection point. The points in the curve $A'(1, \ell)$ belong to $W$-orbits that intersect at least $(a + \ell)$-times the rectangle $R_0$ before intersecting the annulus $A$ and for $\ell > 0$ the endpoint $p'(1; 1, \ell) \in \mathcal{L}_1^\ell$. The genericity assumptions imply thus that the value of $B$ is small. Assume, without loss of generality, that $B = b$ for $b$ as defined in Section [12]

Thus, for $\ell \geq 0$, $A(1, \ell) \subset \mathcal{L}_1^\ell$ is a curve going from the point $p(1; 1, \ell) \in \kappa$ to a point in the boundary of $\partial_n W$ and crossing $A$ at $q(1; 1, \ell) = \sigma_1^{-1}(q'(1; 1, \ell))$, then $A(1, \ell)$ is folded at the point $q(1; 1, \ell)$, as illustrated in Figure [49]. Observe that $q(1; 1, \ell)$ is not necessarily the point of $A(1, \ell)$ with minimum radius, the point with minimum radius of $A(1, \ell)$ is in the arc between $q(1; 1, \ell)$ and $p(1; 1, \ell)$.

![Figure 49. Curves $A'$ and $A'(1, \ell)$ in $\mathcal{L}_1^\ell$ and the corresponding curves in $\mathcal{L}_1^\ell$](image)

Since $A$ and $A(1, \ell)$ intersect, the propellers $P_A$ and $P_{A(1, \ell)}$ intersect along the $W$-orbit of the point $q(1; 1, \ell)$. Observe that $P_{A(1, \ell)}$ is a finite propeller.

We consider now the intersection of $P_{A(1, \ell_1)}$ with $\mathcal{L}_1^\ell$, for $\ell_1 \geq b$. Since $P_{A(1, \ell_1)}$ is a finite propeller the intersection consists of finitely many curves $A'(1, \ell_1; 1, \ell_2)$ for $\ell_1$ fixed and $\ell_2 \geq b$ and bounded. For $\ell_1 \geq 0$ and $\ell_2 \geq 0$, these curves have one endpoint at $p'(1; 1, \ell_1; 1, \ell_2) \subset \kappa'(1, \ell_2)$ and its other endpoint on the boundary of $\mathcal{L}_1^\ell$. Moreover $A'(1, \ell_1; 1, \ell_2)$ is in the region bounded by $\Gamma'(1, \ell_1; 1, \ell_2)$, the later being in the region bounded by $\Gamma'(1, \ell_2)$, by the results of the previous sections. For $\ell_1$ big enough and $\ell_2 \geq 0$ the curve $A'(1, \ell_1; 1, \ell_2)$ intersects $A'$ and at the intersection the curves are transverse to each other. Let $q'(2; 1, \ell_1; 1, \ell_2)$ be the intersection point. Observe that $A'(1, \ell_1; 1, \ell_2)$ also intersects transversally $A'(1, \ell_2)$ at the point $q'(1; 1, \ell_1; 1, \ell_2)$ that is in the $W$-orbit of $q(1; 1, \ell_1)$. The points $q'(1; 1, \ell_2) = A'(1, \ell_2) \cap A'$ and $q'(2; 1, \ell_1; 1, \ell_2)$ are on $A'$ and in the region bounded by $\Gamma'(\ell_2)$, as illustrated in Figure [50].

We comment on the assumption $\ell_1$ big enough. The curve $A'(1, \ell_1; 1, \ell_2)$ intersects $A'$ if its endpoint $p'(1; 1, \ell_1; 1, \ell_2)$ has $z$-coordinate smaller than $-1$, condition that is satisfied for $\ell_1$ big enough since the sequence $p'(1; 1, \ell_1; 1, \ell_2)$ converges to $p'(1; 1, \ell_2)$ as $\ell_1 \to \infty$ and $z(p'(1; 1, \ell_2)) < -1$ for any $\ell_2 \geq a$. Observe that since we want to describe curves at high levels, we just care for curves with $\ell_1$ big. This assumption will be used several times in what follows.

**Remark 18.2.** $A_0$-curves at level 1 have their lower endpoint below the line $z = -1$, since the lower endpoint belongs to a $W$-orbit with radius coordinate equal to 2. At higher levels this is not true. However,
we will only consider $A_0$-curves whose lower endpoint is below $z = -1$. The reason for this is that a higher level $A_0$-curve with lower endpoint above $z = -1$ intersects the domain of the map $\psi^{-1}$. Hence the trace of the propeller containing this $A_0$-curve has curves whose lower endpoint is below $z = -1$. The latter curve is longer, thus an upper bound to the length of the longer curve suffices.

**Lemma 18.3.** For a generic $K$ plug, $r(q'(2; 1, \ell_1; 1, \ell_2)) < r(q'(1; 1, \ell_2))$.

**Proof.** Observe that

$$r(q'(1; 1, \ell_1; 1, \ell_2)) = r(q(1; 1, \ell_1)) \leq r(p(1; 1, \ell_1)) = r(p'(1; 1, \ell_1; 1, \ell_2)),$$

where the two equalities follow since the points are in the same $W$-orbits and the inequality in the middle follows from Hypothesis 17.2. Thus Hypothesis 12.2 implies that the $W$-orbit of $p(1; 1, \ell_1)$ climbs faster than the $W$-orbit of $q(1; 1, \ell_1)$ and thus

$$z(q'(1; 1, \ell_1; 1, \ell_2)) \leq z(p'(1; 1, \ell_1; 1, \ell_2)).$$

For $\ell_1$ big enough and $\ell_2$ bounded, these two $z$-coordinates are less than $-1$. Thus the intersection point of $A'(1, \ell_1; 1, \ell_2)$ and $A'(1, \ell_2)$ has $z$-coordinate less than $-1$, implying that $r(q'(2; 1, \ell_1; 1, \ell_2)) < r(q'(1; 1, \ell_2))$. □

Recall that $A'(1, \ell_1; 1, \ell_2)$ intersects transversally $\kappa'(1, \ell_2) \subset \Gamma'(1, \ell_2)$ at the point $p'(1; 1, \ell_1; 1, \ell_2)$. Since the intersection of $A'(1, \ell_1; 1, \ell_2)$ with $A'(1, \ell_2)$ is also transverse, $A'(1, \ell_1; 1, \ell_2)$ bends at the intersection point $q'(1; 1, \ell_1; 1, \ell_2)$. This implies that the curve $\Gamma'(1, \ell_1; 1, \ell_2)$, that envelops $A'(1, \ell_1; 1, \ell_2)$ and is tangent at $p'(1; 1, \ell_1; 1, \ell_2)$ to $\kappa'(1, \ell_2)$, bends at its intersection with $A'(1, \ell_2)$. The intersection between $\Gamma'(1, \ell_1; 1, \ell_2)$ and $A'(1, \ell_2)$ is transverse and consists of one or two points: $\gamma'(1, \ell_1; 1, \ell_2)$ always intersects $A'(1, \ell_2)$ and $\kappa'(1, \ell_1; 1, \ell_2)$ might intersect it to.

Observe that if we fix the index $\ell_2$ and we let $\ell_1 \to \infty$, both sequences $q'(1; 1, \ell_1; 1, \ell_2)$ and $p'(1; 1, \ell_1; 1, \ell_2)$ converge to the point $p'(1; 1, \ell_2)$.

![Figure 50. Three levels of $A'$-curves inside the region bounded by $\Gamma'(1, \ell_3)$ in $\mathcal{L}_1^-$](image-url)
We now iterate the process above, considering only the first insertion for simplicity. The idea is that a level
$n$ curve in $L^{-}_1$, with $\ell_1$-index big enough, intersects a $A'$-curve at each of the previous levels, and these points are the bending points of the curve.

**Lemma 18.4.** For $\ell_1$ sufficiently large, the curve $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ intersects $A'$ and the curves $A'(1, \ell_{n-k}; \cdots; 1, \ell_n)$ for all $1 \leq k < n$.

For $1 \leq k < n$, the intersection point of $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ with $A'(1, \ell_{n-k}; \cdots; 1, \ell_n)$ is denoted by $q'(k; 1, \ell_1; \cdots; 1, \ell_n)$, and the intersection with $A'$ is denoted by $q'(n; 1, \ell_1; \cdots; 1, \ell_n)$. Observe that the first index in the label of $q$-points is the difference of levels between the $A'$-curves that pass through it.

**Proof.** For $\ell_1$ big enough we can assume that the endpoint $p'(1; 1, \ell_1; \cdots; 1, \ell_n)$ of $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ is in $L^-_1$ and has $z$-coordinate smaller than $-1$, thus the curve intersects $A'$.

We now proceed by induction on $n$. For $n = 1$ the conclusion is straight forward. Assume that the
lemma holds up to $n-1$ and consider the case $n$. For $k = 1$ observe that $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ intersects $\kappa'(1, \ell_2; \cdots; 1, \ell_n)$ at $p'(1; 1, \ell_1; \cdots; 1, \ell_n)$. Following the proof of Lemma 18.3 we have that

$$r(q'(n; 1, \ell_1; \cdots; 1, \ell_n)) < r(q'(n-1; 1, \ell_2; \cdots; 1, \ell_n)).$$

Thus at the line $z = -1$ the curve $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ is on the left of the curve $A'(1, \ell_2; \cdots; 1, \ell_n)$, while near its endpoint it is on the right. These curves intersect.

By hypothesis, the level $n-1$ curve $A'(1, \ell_2; \cdots; 1, \ell_n)$ intersects all the curves of smaller levels. The same holds for the curve $\Gamma'(1, \ell_2; \cdots; 1, \ell_n)$; that is, $\Gamma'(1, \ell_2; \cdots; 1, \ell_n)$ intersects the curves $A'(1, \ell_{n-k}; \cdots; 1, \ell_n)$ for all $2 \leq k < n$. Since $A'(1, \ell_1; 1, \ell_2; \cdots; 1, \ell_n)$ is in the region bounded by $\Gamma'(1, \ell_2; \cdots; 1, \ell_n)$, we obtain that

$$r(q'(1; 1, \ell_1; 1, \ell_2)) < r(q'(2; 1, \ell_1; 1, \ell_2)).$$

Thus the finite propeller $P_{A(1, \ell_1; 1, \ell_2)}$ intersects:

- $\sigma_1^{-1}(A'(1, \ell_1; 1, \ell_2)) \subset L^-_1$ intersects transversally:
  - $A(1, \ell_2)$ at the point $q(1; 1, \ell_1; 1, \ell_2)$.
  - $A$ at the point $q(2; 1, \ell_1; 1, \ell_2)$.

Thus the finite propeller $P_{A(1, \ell_1; 1, \ell_2)}$ intersects:

- $P_{A(1, \ell_2)}$ along the $W$-orbit of $q(1; 1, \ell_1; 1, \ell_2)$.
- $P_A$ along the $W$-orbit of $q(2; 1, \ell_1; 1, \ell_2)$.

Consider the trace of $P_{A(1, \ell_1; 1, \ell_2)}$ on $L^-_1$, that forms a finite collection of curves $A'(1, \ell_1; 1, \ell_2; 1, \ell_3)$ with $\ell_3 \geq b$ and bounded. For $\ell_3 \geq 0$ we have that:

- $A'(1, \ell_1; 1, \ell_2; 1, \ell_3)$ is contained in the region bounded by $\Gamma'(1, \ell_1; 1, \ell_2; 1, \ell_3)$, which is contained in the region bounded by $\Gamma'(1, \ell_2; 1, \ell_3)$, that is in the region bounded by $\Gamma'(1, \ell_3)$, by the nesting property.
- $A'(1, \ell_1; 1, \ell_2; 1, \ell_3)$ intersects $A'(1, \ell_2; 1, \ell_3)$ at $q'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$; $A'(1, \ell_3)$ at $q'(3; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and $A'$ at $q'(3; 1, \ell_1; 1, \ell_2; 1, \ell_3)$. Applying the proof of Lemma 18.3 we have that

$$r(q'(3; 1, \ell_1; 1, \ell_2; 1, \ell_3)) < r(q'(2; 1, \ell_2; 1, \ell_3)) < r(q'(1; 1, \ell_3)).$$

Thus the curve $A'(1, \ell_1; 1, \ell_2; 1, \ell_3)$ folds twice: once at $q'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and once at $q'(2; 1, \ell_1; 1, \ell_2; 1, \ell_3)$. We deduce that the corresponding $A_0$-curve in $R_0$, $A_0(1, \ell_1; 1, \ell_2; 1, \ell_3)$, folds twice near each of its endpoints due to the symmetry condition on the Wilson flow. Recall that $A_0(1, \ell_1; 1, \ell_2; 1, \ell_3) \subset R_0$ is the curve containing points whose forward orbits intersect $E_1$ along $\tau(A(1, \ell_1; 1, \ell_2; 1, \ell_3))$.

Iterating this analysis we get that each $A'$-curve at level $n$ folds $(n-1)$-times, and thus the lower end part of the corresponding $A_0$-curve coils in a “small” spiral turning in the counter-clockwise direction.

We can now start the proof of Theorem 18.1 that is a direct consequence of the following proposition.
PROPOSITION 18.5. The length of an $A_0$-curve is upper bounded by the length of $A_0(a) + D$ for some uniform constant $D$.

Proof. As explained in Remark 18.2 we can restrict to curves whose lower endpoint is below $z = -1$. We start by comparing the length of $A_0(1, \ell_1; \ell_2)$ with the length of $A_0(\ell_2)$. The idea is to prove first that

$$\text{length}(A_0(1, \ell_1; \ell_2)) < \text{length}(A_0(\ell_2)) + D,$$

that is clearly upper bounded by the length of $A_0(a) + D$.

The curve $A'(1, \ell_1; \ell_2)$ in $\mathcal{L}_1^-$ can be decomposed into two parts: the one between $p'(1;1,\ell_1;1,\ell_2)$ and $q'(1;1,\ell_1;1,\ell_2)$ and the rest. Observe that the later part has approximately the same length as the segment of $A'(1,\ell_2)$ that lies above (in the $z$-direction) the point $q'(1;1,\ell_1;1,\ell_2)$. The reason for this is that both curves are in the region bounded by $\Gamma'(1,\ell_2)$ and have no bending points above $q'(1;1,\ell_1;1,\ell_2)$.

We can thus bound the length of $A'(1,\ell_1;1,\ell_2)$ by the sum of the length of $A'(1,\ell_2)$ plus the distance between the points $p'(1;1,\ell_1;1,\ell_2)$ and $q'(1;1,\ell_1;1,\ell_2)$. We compare the distances in $R_0$. Translating the discussion above to $R_0$, we can bound the length of $A_0(1,\ell_1;\ell_2)$ by the sum of the length of $A_0(\ell_2)$ plus twice the distance between $p_0(1;1,\ell_1;1,\ell_2)$ and $q_0(1;1,\ell_1;1,\ell_2)$. The multiplication by two is due to the symmetry of these curves with respect to the line $\{z = 0\}$. Let $\varphi_{\ell_2} = \psi^{a+\ell_2} \circ \phi_1^+ \in G_K$, then using Lemmas 13.6 and 13.7 we obtain

$$d_{R_0}(p_0(1;1,\ell_1;1,\ell_2), q_0(1;1,\ell_1;1,\ell_2)) = d_{R_0}(\varphi_{\ell_2}(p_0(1;1,\ell_1)), \varphi_{\ell_2}(q_0(1;1,\ell_1))).$$

The next lemma is the key ingredient in the proof. Recall that $U_{\phi_1^+}$ is the domain of the map $\phi_1^+$. Let $D'(1,\ell)$ be the points in the region bounded by $\Gamma_0(\ell)$ that belong to $U_{\phi_1^+} \cap \{z \leq -1\}$. Define

$$D(1,\ell) = \{x \in D'(1,\ell) \mid \varphi_\ell(x) \in D'(1,\ell)\},$$

for $\varphi_\ell = \psi^{a+\ell} \circ \phi_1^+$.

**LEMMA 18.6.** For a generic Kuperberg plug $\mathbb{K}$, the norm of the differential of $\varphi_\ell = \psi^{a+\ell} \circ \phi_1^+$ is less than 1 for points in $D(1,\ell)$.

Proof. Observe that $\psi^{-(a+\ell)}(D(1,\ell))$ is contained in the region of $R_0$ bounded by $\Gamma_0(a)$. The map $\psi$ preserves the $r$-coordinate. The map $\phi_1^+$ maps $D(1,\ell)$ to the interior of the region bounded by $\Gamma_0(a)$, and thus

$$\text{Image}(\phi_1^+ D(1,\ell)) \subseteq \text{Image}(\psi^{-(a+\ell)}(D(1,\ell))).$$

For every $\ell' \geq \ell$ such that the region $D(1,\ell') \neq \emptyset$, we have that

$$\text{Image}(\phi_1^+ D(1,\ell')) \subseteq \text{Image}(\psi^{-(a+\ell)}(D(1,\ell))).$$

Thus for points in $D(1,\ell)$ the map $\phi_1^+$ contracts distances more than $\psi^{-(a+\ell)}$. Hence, the norm of the differential of $\phi_1^+$ is smaller than the norm of the differential of $\psi^{-(a+\ell)}$ for any $\ell'$ such that $D(1,\ell')$ is non-empty. Hence, for $\xi \in D(1,\ell)$ we have that

$$\|D\varphi_\ell(\xi)\| \leq \|D\psi^{(a+\ell)}(\phi_1^+ (\xi))\| \times \|D\phi_1^+(\xi)\|$$

$$< \|D\psi^{(a+\ell)}(\phi_1^+(\xi))\| \times \|D\psi^{-(a+\ell)}(\psi^{a+\ell} \circ \phi_1^+(\xi))\|$$

$$= \|D\psi^{(a+\ell)}(\eta)\| \times \|D\psi^{-(a+\ell)}(\psi^{a+\ell}(\eta))\| = 1.$$

where $\eta = \phi_1^+(\xi)$. The last equality uses the fact that $\psi$ preserves the $r$-coordinate. \quad \Box

Observe that for $\xi \in D(1,\ell)$ and $\ell' \geq \ell$ we have also that $\|D\varphi_{\ell'}(\xi)\| < 1$, provided $z(\varphi_{\ell'}(\xi)) \leq -1$.

We come back to bounding the length of the level 2 curve $A_0(1, \ell_1; \ell_2)$. From (121) and the previous lemma, we obtain a constant $C < 1$ such that

$$d_{R_0}(p_0(1;1,\ell_1;1,\ell_2), q_0(1;1,\ell_1;1,\ell_2)) \leq C d_{R_0}(p_0(1;1,\ell_1), q_0(1;1,\ell_1)).$$
Let $a_1 = \max_{t_1 \geq 0} \{ d_{R_0}(p_0(1; 1, \ell_1), q_0(1; 1, \ell_1)) \}$ then,

$$\text{length}(A_0(1, \ell_1; \ell_2)) \leq \text{length}(A_0(\ell_2)) + 2Ca_1,$$

concluding the proof of Proposition 18.5 for level 2 curves for any $D \geq 2Ca_1$.

We now consider the level 3 case. Again the curve $A'(1, \ell_1; 1, \ell_2; 1, \ell_3) \subset \mathcal{L}_3^-$ can be decomposed into two parts: the one between $p'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and $q'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and the rest. The latter part has approximately the same length as the part of $A'(1, \ell_2; 1, \ell_3)$ that lies above the point $q'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$. Thus the length of $A'(1, \ell_1; 1, \ell_2; 1, \ell_3)$ is upper bounded by the length of $A'(1, \ell_2; 1, \ell_3)$ plus the distance between the points $p'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and $q'(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$.

In $R_0$, the length of $A_0(1, \ell_1; 1, \ell_2; \ell_3)$ is bounded above by the length of $A_0(1, \ell_2; \ell_3)$ plus twice the distance between the points $p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$ and $q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)$. Observe that for $\varphi_{\ell_3} = \psi^{(n+\ell_3)} \circ \phi_1^n$ we have that $p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3) = \varphi_{\ell_3}(p_0(1; 1, \ell_1; 1, \ell_2))$ and $q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3) = \varphi_{\ell_3}(q_0(1; 1, \ell_1; 1, \ell_2))$. By construction the point $p_0(1; 1, \ell_1; 1, \ell_2)$ belongs to the curve $\kappa_0(\ell_2) \subset \Gamma_0(\ell_2)$ and $q_0(1; 1, \ell_1; 1, \ell_2)$ belongs to $A_0(\ell_2)$. Thus these two points are in $D(1, \ell_2)$. By Lemma 18.6 and $C < 1$ as above, we obtain

$$d_{R_0}(p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3), q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)) \leq C d_{R_0}(p_0(1; 1, \ell_1; 1, \ell_2), q_0(1; 1, \ell_1; 1, \ell_2)) \leq C^2 d_{R_0}(p_0(1; 1, \ell_1), q_0(1; 1, \ell_1)) \leq C^2 a_1.$$

Thus,

$$\text{length}(A_0(1, \ell_1; 1, \ell_2; \ell_3)) \leq \text{length}(A_0(1, \ell_2; \ell_3)) + 2d_{R_0}(p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3), q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)) \leq \text{length}(A_0(\ell_3)) + 2Ca_1 + 2C^2 a_1 = \text{length}(A_0(\ell_3)) + 2Ca_1(1 + C).$$

The first inequality follows just by decomposing the lower half of $A_0(1, \ell_1; 1, \ell_2; \ell_3)$ it two parts and using the symmetry of this curve with respect to $\{z = 0\}$. The second inequality follows from the estimation of the length of level 2 curves and the computation above.

Iterating this argument for level 4 curves we have that

$$\text{length}(A_0(1, \ell_1; 1, \ell_2; 1, \ell_3; \ell_4)) \leq \text{length}(A_0(1, \ell_2; 1, \ell_3; \ell_4)) + 2d_{R_0}(p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3), q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3; 1, \ell_4)) \leq \text{length}(A_0(\ell_4)) + 2Ca_1(1 + C) + 2C d_{R_0}(p_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3), q_0(1; 1, \ell_1; 1, \ell_2; 1, \ell_3)) \leq \text{length}(A_0(\ell_4)) + 2Ca_1(1 + C) + 2C^2 a_1 = \text{length}(A_0(\ell_4)) + 2Ca_1(1 + C + C^2).$$

Generalizing to a level $n$ curve, we get

$$\text{length}(A_0(1, \ell_1; \cdots; 1, \ell_n)) \leq \text{length}(A_0(\ell_n)) + 2Ca_1(1 + C + \cdots + C^{n-2}) = \text{length}(A_0(\ell_n)) + 2a_1 \left( \frac{C - C^n}{1 - C} \right).$$

The last amount is upper bounded by $\frac{C}{1-C}$, and thus taking $D = \max\{2a_1 \left( \frac{C}{1-C} \right), 2a_1 \}$ we obtain the desired bound.

This finishes the proof of Theorem 18.1. We can now describe a more accurate picture of the trace on $R_0$ of a level $n \geq 2$ propeller in $\mathfrak{M}_0$ and thus of the trace of $\mathfrak{M}_0$. In Figure 20 we had made the assumption that the curve generating a finite propeller has monotone radius and thus that the longest $W$-orbit in the propeller
is the orbit of the endpoint of the curve. As described above, the propellers in \( M_0 \) of level at least 2 are not generated by curves with monotone radius.

Consider a curve \( \gamma(i_1, \ell_1; \cdots; i_n, \ell_n) \subset L_i \) with \( n \geq 2 \), \( i_k = 1, 2 \) for \( 1 \leq k \leq n \) and non monotone radius. Once more, we restrict the discussion to \( \gamma \)-curves for simplicity, but it applies also to \( \lambda \)-curves.

Let \( q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n) \) be the point in \( \gamma(i_1, \ell_1; \cdots; i_n, \ell_n) \) with smaller radius. The trace of the propeller \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \subset \mathcal{W} \) on \( \mathcal{R}_0 \) consists of at most

\[
\Delta(r(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n))) + 1
\]
curves, one for each intersection of the \( \mathcal{W} \)-orbit of \( q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n) \) with \( \mathcal{R}_0 \cap \{ z \leq 0 \} \). Call this number \( n(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n)) \). Recall that the \( \mathcal{W} \)-orbit of \( p(1; i_1, \ell_1; \cdots; i_n, \ell_n) \) intersects \( \mathcal{R}_0 \cap \{ z \leq 0 \} \) in at most \( \Delta(r(p(1; i_1, \ell_1; \cdots; i_n, \ell_n))) + 1 \) points. Call this number \( n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) \). Hence the trace of \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) on \( \mathcal{R}_0 \) are the curves \( \gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; 0) \) with \( a \leq \ell_{n+1} \leq n(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n)) \).

If \( n(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n)) - n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) \geq 0 \), then for

\[
n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) < \ell_{n+1} \leq n(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n))
\]
the curves \( \gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \) are closed, as in Figure 51. The closed curves are contained in the region

\[
\{ r(q^\gamma(n; i_1, \ell_1; \cdots; i_n, \ell_n)) \leq r < r(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) \} \cap \mathcal{R}_0.
\]

In conclusion, the trace of \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) on \( \mathcal{R}_0 \) can have a non-zero but finite number of closed curves.

We now turn our attention once more to the intersection of \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) with \( \mathcal{L}_0^- \). As explained in Section 12 the intersection consists of a number of internal notches, followed by boundary notches. After the description in this section two new possibilities arise. First, since the radius is non monotone along the curves in \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \cap \mathcal{R}_0 \), some of these curves might create internal notches when flowed to \( \mathcal{L}_0^- \). Second, the fact that the trace of \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) on \( \mathcal{R}_0 \) can have closed curves adds the possibility of having internal notches near the tip of the propeller, as illustrated in Figure 52.

![Figure 51. Trace of the finite propeller](image)

The two level 1 propellers \( \tau(P_i) \) and \( \tau(P_i^a) \) in \( M_0 \) are generated by curves with monotone radius. Thus they have a finite number \( |b| \geq 0 \), maybe zero, of internal notches and an infinite number of (boundary) notches, as described in Section 13. If any, the internal notches generate bubbles as in Section 14.

Consider the case of propellers of level at least 2. Let \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) be a propeller of level \( n + 1 \geq 2 \). Let \( \gamma'(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}) \subset \mathcal{L}_1^- \) be the curves in the intersection of \( P_{\gamma(i_1, \ell_1; \cdots; i_n, \ell_n)} \) with \( \mathcal{L}_1^- \) and \( \gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \) the corresponding curve in \( \mathcal{R}_0 \). Internal notches arise when \( \gamma'(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}) \) has its two endpoints in \( \partial \mathcal{L}_1^- \).
Assume that this is the case. If the corresponding curve $\gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset R_0$ is not a closed curve, then the forward orbit of its lower endpoint $p_0(1; i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1})$ misses $L_1^-$. Thus the radius coordinate along the curve $\gamma(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}) \subset L_1^-$ is big, meaning that it is uniformly bounded below. The arguments in Section 15 apply to this case and thus the surface generated by the $K$-coordinate along the curve $\gamma$ is compact and admits a uniform upper bound to the difference of level between points in it. We leave the details to the reader.

For the second case, assume that $\gamma'(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1})$ has its two endpoints in \(\partial L_1^-\) and that the corresponding curve $\gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset R_0$ is a closed curve. This means that

$$n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n)) - n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) > 0$$

and $n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) < \ell_{n+1} \leq n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n))$.

**Lemma 18.7.** There exists $r_B > 2$ such that if $n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n)) - n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) > 0$ the radius coordinate on the curves $\gamma(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}) \subset L_1^-$ with $n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) < \ell_{n+1} \leq n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n))$ is bounded below by $r_B$.

**Proof.** Observe that the closed curve $\gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset R_0$ is contained in the region bounded by $\Gamma_0(i_2, \ell_2; \cdots; \ell_{n+1})$ if $i_1 = 1$ and in the region bounded by $\Lambda_0(i_2, \ell_2; \cdots; \ell_{n+1})$ if $i_1 = 2$. Also, it is far from $\Gamma_0(i_2, \ell_2; \cdots; \ell_{n+1})$ or $\Lambda_0(i_2, \ell_2; \cdots; \ell_{n+1})$ since the point $p_0(i_1; i_2, \ell_2; \cdots; 1, \ell_{n+1})$ is in the closure of the endpoints of the curves $\gamma_0(i_1, m; \cdots; i_n, \ell_n; \ell_{n+1})$ that are arcs, for $m > \ell_1$ and unbounded. That is $\gamma_0(i_1, \ell_1; \cdots; \ell_{n+1})$ is separated from $\Gamma_0(i_2, \ell_2; \cdots; \ell_{n+1})$ or $\Lambda_0(i_2, \ell_2; \cdots; \ell_{n+1})$ by the curves $\gamma_0(i_1, m; \cdots; \ell_{n+1})$ and $\lambda_0(i_1, m; \cdots; \ell_{n+1})$ for all $m > \ell_{n+1}$.

Assume the conclusion in the lemma is false, then for every $\epsilon > 0$ there exists a curve $\gamma(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}) \subset L_1^-$ with

$$n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) < \ell_{n+1} \leq n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n))$$

intersecting the ball centered at $p(1)$ of radius \(\epsilon\). Equivalently, for every $\epsilon > 0$ there exists a closed curve $\gamma_0(i_1, \ell_1; \cdots; i_n, \ell_n; \ell_{n+1}) \subset R_0$ with

$$n(p(1; i_1, \ell_1; \cdots; i_n, \ell_n)) < \ell_{n+1} \leq n(q^{\gamma}(n; i_1, \ell_1; \cdots; i_n, \ell_n))$$

intersecting the ball centered at $\omega_1$ of radius \(\epsilon\). Thus there is a sequence of closed curves accumulating on $\omega_1$ that belong to the trace of the propellers. This is the contradiction that we needed.

**Remark 18.8.** An immediate consequence of Lemma 18.7 is that the surfaces given by the $K$-orbits of the points in $\tau(\gamma(i_1, \ell_1; \cdots; i_n, \ell_n; 1, \ell_{n+1}))$, with $\ell_{n+1}$ satisfying the hypotheses of the lemma, are compact and
The difference of level between points in them is uniformly bounded as in Proposition 15.4. We refer to these surfaces as bubbles of the second type.

19. Zippered laminations

The notion of an n-dimensional lamination is well-known, and can be summarized as an n-dimensional foliated space which is transversally modeled on a totally disconnected space. In this section, we introduce the notion of zippered laminations, which are a type of “stratified” laminations with possibly pathological behavior for the strata. After introducing this and some other preliminary notions, we prove the main result of this section:

**THEOREM 19.1.** If \( \Phi_t \) is a generic Kuperberg flow on \( \mathbb{K} \), then \( \mathcal{M} \) is a zippered lamination.

We begin by recalling the notion of a foliated space \([7, 38]\). A **continuum** is a non-empty, compact, connected metric space.

**DEFINITION 19.2.** A foliated space of dimension \( n \) is a continuum \( \mathfrak{F} \) with a foliated structure. That is, there exists:

1. a separable metric space \( \mathbb{X} \), and a collection of compact subsets \( \mathcal{F} \subset \mathbb{X} \) for \( 1 \leq i \leq k \);
2. a finite collection of homeomorphisms (the charts) \{\( \varphi_i : \mathcal{F} \times [-1,1]^n \to \mathcal{U}_i \subset \mathfrak{F} | 1 \leq i \leq k \} \);
3. the “interiors” \( \{U_i = \varphi_i(\mathcal{F} \times (-1,1)^n) | 1 \leq i \leq k \} \) form an covering for \( \mathfrak{F} \);
4. the charts \{\( \varphi_i | 1 \leq i \leq k \) satisfy the compatibility condition \([123]\).

Let \( \pi_i : \mathcal{U}_i \to \mathcal{F} \) denote the composition of \( \varphi_i^{-1} \) with projection onto the first factor.

For \( \xi \in \mathcal{F} \), the set \( \mathcal{P}_i(\xi) = \varphi_i(\{\xi\} \times [-1,1]^n) \subset \mathcal{U}_x \) is called a plaque for the coordinate chart \( \varphi_i \). For \( z \in \mathcal{U}_i \), we adopt the notation \( \mathcal{P}_i(z) = \mathcal{P}_i(\pi_i(z)) \), so that \( z \in \mathcal{P}_i(z) \).

For \( \xi \in \mathcal{F} \), the plaque \( \mathcal{P}_i(\xi) \) is given the topology so that the restriction \( \varphi_i : \{\xi\} \times [-1,1]^n \to \mathcal{P}_i(\xi) \) is a homeomorphism, hence \( \text{int}(\mathcal{P}_i(\xi)) = \varphi_i(\{\xi\} \times (-1,1)^n) \). Then we require, in addition,

\[
\text{(123)} \quad \text{for all } z \in U_i \cap U_j, \quad \text{int}(\mathcal{P}_i(z)) \cap \text{int}(\mathcal{P}_j(z)) \text{ is an open subset of both } \mathcal{P}_i(z) \text{ and } \mathcal{P}_j(z).
\]

The collection of sets \( \mathcal{V} = \{\varphi_i(\{\xi\} \times V) \leq i \leq k, \xi \in \mathcal{F}, V \subset (-1,1)^n \text{ open}\} \) forms the basis for the **fine topology** of \( \mathfrak{F} \). The connected components of the fine topology are called leaves, and define the foliation \( \mathcal{F} \) of \( \mathfrak{F} \). For \( x \in \mathfrak{F} \), let \( L_x \subset \mathcal{M} \) denote the leaf of \( \mathcal{F} \) containing \( x \). The subsets \( \mathcal{F}_i \) of \( \mathbb{X} \) are called the **local transverse models**.

Many of the techniques of foliation theory extend to foliated spaces, including the existence of holonomy transformations defined by “parallel transport” along paths in the leaves, which generate a pseudogroup model for the dynamics of the foliated space. Foliated spaces are considered in greater detail in \([38, \text{Chapter 2}] \) and \([7, \text{Chapter 11}] \).

An **n-dimensional lamination** is a foliated space \( \mathfrak{F} \) of dimension \( n \), such that the transverse model space \( \mathbb{X} \) is totally disconnected. The leaves of \( \mathcal{F} \) are then the path components of \( \mathfrak{F} \).

The definition of a **lamination with boundary** is obtained by modifying the above definition, to allow foliation charts of the form \( \varphi_i : \mathcal{F} \times ([0,1) \times (-1,1)^{n-1}) \to U_i \). The boundary \( \partial \mathfrak{F} \) then consists of the points which are images under a chart of the chart boundary \( \mathcal{F} \times \{(0) \times (-1,1)^{n-1}\} \).

The notion of a “zippered lamination” is motivated by our study of the space \( \mathcal{M} \), which is the closure of the non-compact manifold with boundary \( \mathcal{M}_0 \). The unusual property of \( \mathcal{M} \) is that the boundary curves of \( \mathcal{M}_0 \) are also dense in \( \mathcal{M} \), which is impossible for a usual lamination with boundary. The definition of a zippered lamination below is similar to that of a lamination with boundary, in that each of its leaves is a manifold with boundary, but the boundaries of the leaves do not have to align themselves in a way that they are regularly covered by foliation charts. In place of the covering of \( \mathcal{M} \) by standard foliation coordinate charts as in
Definition [19.2] the definition below covers \( \mathcal{M} \) by foliation coordinate charts whose plaques have varying sizes, and cannot be “standardized” in a continuous manner, though their overlaps do define continuous holonomy transformations.

**Definition 19.3.** An \( n \)-dimensional zippered lamination \( \mathfrak{Z} \) is a continuum whose path components are \( n \)-dimensional manifolds with boundary. Denote the union of the boundaries of the leaves by \( \partial_\mathfrak{Z} \mathfrak{Z} \), and the complement by \( \text{int}(\mathfrak{Z}) = \mathfrak{Z} - \partial_\mathfrak{Z} \mathfrak{Z} \). Then we require that \( \text{int}(\mathfrak{Z}) \) is dense in \( \mathfrak{Z} \), and the following data are given, which satisfies the accompanying conditions: there is given a compact metric space \( X \) and \( \{ \xi \} \times [0, 1]^n \) is a compact subset whose interior contains \( \{ \xi \} \times \{ 0 \} \), and is homeomorphic to \([0, 1]^n\).

- (1) a subset \( \mathcal{F}_i \subset X \) whose closure in \( X \) is totally disconnected;
- (2) a Borel subset \( \mathcal{B}_i \subset \mathcal{F}_i \times [-1, 1]^n \), where for each \( \xi \in \mathcal{F}_i \) the slice \( \mathcal{B}_i \cap \{ \xi \} \times [-1, 1]^n \) is a compact subset whose interior contains \( \{ \xi \} \times \{ 0 \} \); and is homeomorphic to \([0, 1]^n\);
- (3) a homeomorphism \( \varphi_i : \mathcal{B}_i \to \mathcal{U}_i \subset \mathfrak{Z} \) onto its image \( \mathcal{U}_i \) with the induced topology from \( \mathfrak{Z} \);
- (4) the interiors \( \{ U_i = \text{int}(\mathcal{U}_i) \mid 1 \leq i \leq k \} \) form a covering for \( \text{int}(\mathfrak{Z}) \);
- (5) the collection of charts \( \{ \varphi_i \mid 1 \leq i \leq k \} \) satisfy the compatibility condition (123).

The interior \( \text{int}(\mathcal{U}_i) \) for the Borel set \( \mathcal{U}_i \) is defined as the union over the points \( \xi \in \mathcal{F}_i \) of the interiors of the plaques \( \mathcal{P}_i(\xi) = \varphi_i(\mathcal{B}_i \cap \{ \xi \} \times [-1, 1]^n) \) in \( \mathcal{U}_i \).

Note that the Borel property in 19.3.2 allows the plaques \( \mathcal{P}_i(\xi) \subset \mathfrak{Z} \) to degenerate in size for a sequence \( \xi_i \in \mathcal{F}_i \), which converges to a point \( \xi_* \in X \) with \( \xi_* \notin \mathcal{F}_i \). In fact, the limit of such a sequence must then be contained in \( \partial_\mathfrak{Z} \mathfrak{Z} \).

The first step in showing that \( \mathcal{M} \) satisfies the conditions of Definition [19.3] is to construct the model spaces \( \mathcal{F}_i \). Recall that \( \mathcal{T} = \{ z = 0 \} \cap \mathcal{R}_0 \), and set:

\[
(124) \quad \mathcal{C}_0 = \mathcal{C} \cap \mathcal{M}_0, \quad \mathcal{C}' = \mathcal{T} \cap \mathcal{M}.
\]

The points in \( \mathcal{C}_0 \) are classified according to the properties of the curves in \( \mathcal{M}_0 \cap \mathcal{R}_0 \) which define them. The intersection of \( \mathcal{T} \) with the Reeb cylinder \( \tau(\mathcal{C}') \) defines the point \( \omega_0 \in \mathcal{M}_0 \cap \mathcal{R}_0 \) with \( r(\omega_0) = 2 \). The remaining points in the intersection correspond to the intersections with \( \gamma_0 \) or \( \lambda_0 \) curves, and these can be of two types:

1. The \( \gamma_0 \) or \( \lambda_0 \) curve is an arc. In the case where the forward orbit of points in such a curve hit the entry regions, the curve corresponds to boundary notches in the propeller, one for each entry region.
2. The \( \gamma_0 \) or \( \lambda_0 \) curve is a closed curve, hence there are two points in \( \mathcal{C}_0 \) corresponding to the same curve. In the case where the forward orbit of points in such a curve hit the entry regions, the curve corresponds to interior notches in the propeller, either one or two for each entry region. These closed curves correspond either to notches generating “bubbles” or to intersections of “bubbles” with \( \mathcal{R}_0 \) as described in Sections [15] and [18].

Let \( \mathcal{C}_1 \subset \mathcal{C}_0 \) be the intersection points corresponding to closed curves in \( \mathcal{M}_0 \cap \mathcal{R}_0 \). Define:

\[
(125) \quad \mathcal{C}_0 = \mathcal{C}_0 \setminus \mathcal{C}_1, \quad \mathcal{C} = \overline{\mathcal{C}_0}.
\]

**Proposition 19.4.** The set \( \mathcal{C} \) is a perfect and totally disconnected subset of \( \mathcal{C}' \).

**Proof.** Each point in \( \mathcal{C}_0 \) is the intersection of \( \mathcal{T} \) with a certain \( \gamma_0 \) or \( \lambda_0 \) curve, and thus is defined by the labeling of the endpoints of this curve as in Section [12]. Moreover, the symmetry of the Wilson flow implies that each such \( \gamma_0 \) and \( \lambda_0 \) curve in \( \mathcal{M}_0 \cap \mathcal{R}_0 \) intersects \( \mathcal{T} \). Thus, a sequence of curves whose intersections with \( \mathcal{T} \) defines points in \( \mathcal{C}_0 \) which converge, also defines a sequence of converging endpoints, whose corresponding limit curve defines a point in \( \mathcal{M} \cap \mathcal{T} \). Thus, \( \mathcal{C} = \overline{\mathcal{C}_0} \subset \mathcal{M} \cap \mathcal{T} = \mathcal{C}' \). Lemma [13.10] implies that each point of \( \mathcal{C}_0 \) is a limit point of the set, hence the closure \( \mathcal{C} \) is a perfect set. It is totally disconnected by the results of Section [16].

**Remark 19.5.** It can also be proved that \( \mathcal{C}' \) is a Cantor set, since any \( q^\gamma \) or \( q^\lambda \) point is the accumulation point of a sequence of \( q^\gamma \) and \( q^\lambda \) points of lower level.
The strategy for constructing foliation charts for $\mathcal{M}$ using the Cantor set $\mathcal{C}$ is simple in outline, and we next develop. But there is a nuance that arises near points of $\mathcal{C}$ corresponding to tips of propellers, that requires covering these “singular points” by a separate construction.

Consider $\xi \in \mathcal{C} - \mathcal{C}_0$, then there exists $\{x_k : k \geq 1\} \subset \mathcal{C}_0$ with $x_k \to \xi$. By the results of Section 12 each $x_k$ lies on a propeller curve $\gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n)$ or $\lambda_0(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n)$ where the multi-index depends on $k$. By passing to a subsequence, we can assume that they are all of the same type, either all $\gamma_0$ curves, or all $\lambda_0$ curves. Each such curve is then defined by the labeling of its endpoints, denoted simply by $p_0^n(x_k)$ to shorten the notation introduced in Section 13. That is, $p_0^n(x_k) = p_0(i_0; i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n)$ for $i_0 = 1$ for a $\gamma_0$ curve, and $i_0 = 2$ for a $\lambda_0$ curve.

We consider the case where we have a sequence of $\gamma_0$ curves. The case for a sequence of $\lambda_0$ curves is analogous. As $R_0$ is compact, we can pass to a subsequence, and assume that the lower endpoints $p_0^n(x_k)$ converge to a point $p_0^0(\xi)$ where $z(p_0^0(\xi)) \leq 0$, and similarly $p_0^0(x_k) \to p_0^0(\xi)$ where $z(p_0^0(\xi)) \geq 0$.

The sequence of endpoints $p_0^n(x_k)$ all lie on the $K$-orbit of the special point $\omega_1$, so each has a well-defined level by Proposition 10.1. If there is a uniform bound on this level, then the limit must be contained in $\mathcal{M}_0$ contrary to the choice of $\xi$. Thus, passing to a subsequence yet again, we can assume that the level $n_0(x_k)$ is monotone increasing.

It then follows that the number $n$ of indices of the sequence $\gamma_0(i_1, \ell_1; i_2, \ell_2; \cdots ; i_n, \ell_n)$ must tend to infinity, and by the results of Section 13, the sequence $\{x_k\}$ defines a nested sequence of ellipses in $R_0$, each ellipse bounded by the union of the associated $\gamma_0$ and $\lambda_0$ curves. Moreover, the width of these ellipses must tend to zero. It follows that the intersections of the interiors of these nested ellipses define an arc in $R_0$, denoted by $\tilde{[p_0^n(\xi), p_0^0(\xi)]}$ where the point $\tilde{\xi} = [p_0^n(\xi), p_0^0(\xi)] \cap \{z = 0\}$.

The arc $[p_0^n(\xi), p_0^0(\xi)]$ is the limit of the boundary $\gamma_0$ curves of the nested ellipses, as a point set. Each of these boundary $\gamma_0$ curves is an embedded curve with uniformly bounded length by Theorem 18.1. Thus, these curves converge to an immersed arc of finite length. That is, in a generic Kuperberg plug, for $\xi \in \mathcal{C}$ the curve $[p_0^n(\xi), p_0^0(\xi)]$ has uniformly bounded arclength.

We next repeat these arguments for each of four rectangular sections to $\mathcal{M}$, defined as follows, and the associated Cantor transversals. Introduce the rectangles

$$T_i = \{\xi = (r, i \cdot \pi/2, z) \mid 1 \leq r \leq 3, \ -2 \leq z \leq 2\}, \ 1 \leq i \leq 4$$

so that $R_0 = T_2$. We add a fifth rectangle

$$T_5 = \{\xi = (r, 3\pi/8, z) \mid 1 \leq r \leq 3, \ -2 \leq z \leq 2\}.$$

Each of these rectangles is disjoint from both the regions $D_i$ and their insertions $\mathcal{D}_i$ for $i = 1, 2$ by the choices made in Section 3. It is helpful to review the illustrations in Figures 5 and Figure 8. The key property of these sections that we require, is that for any $K$-orbit segment $[x, y]_K$ with $x, y \in T_i$, then either the interior segment $(x, y)_K$ intersects the annulus $\mathcal{A}$, or it must intersect one of the other sections $T_j$ for $j \neq i$.

For each of $1 \leq i \leq 5$, introduce the set $\mathcal{C}_{0,i} \subset T_i \cap \mathcal{A} \cap \mathcal{M}_0$ consisting of the points that do not belong to a bubble of any type, and correspond to arcs in $T_i \cap \mathcal{M}_0$. Note that $\mathcal{C}_{0,2} = \mathcal{C}_0$. Define $\mathcal{C}_i$ to be the closure of $\mathcal{C}_{0,i}$. We again conclude that each $\xi \in \mathcal{C}_i$ defines an immersed arc $[p_1^n(\xi), p_1^0(\xi)]$, each of whose length admits a uniform upper bound.

For each $1 \leq i \leq 5$, define functions $S^+_i : \mathcal{C}_i \to [0, \infty)$ such that for $\xi \in \mathcal{C}_i$

- $S_i^+(\xi)$ is the length of the arc $[\xi, p_1^n(\xi)] \subset [p_1^n(\xi), p_1^0(\xi)]$ containing $\xi$ as the lower endpoint, where $[\xi, p_1^n(\xi)] \subset \{z \geq 0\}$;
- $S_i^-(\xi)$ is the length of the arc $[p_1^n(\xi), \xi] \subset [p_1^n(\xi), p_1^0(\xi)]$ containing $\xi$ as the upper endpoint, where $[p_1^n(\xi), \xi] \subset \{z \leq 0\}$.

Since $\tau^{-1}(p_2^n(\xi))$ and $\tau^{-1}(p_1^n(\xi))$ belong to the same $W$-orbit, the symmetry of the $\Psi_i$-flow implies that $S_i^+(\xi) = S_i^-(\xi)$. Let $S_i(\xi) = S_i^+(\xi)$. Then by the above, for each $i$, the function $\xi \mapsto S_i(\xi)$ admits a uniform upper bound for all $\xi \in \mathcal{C}_i$. Let $L_i = \sup\{S_i(\xi) : \xi \in \mathcal{C}_i\}$ denote the upper bound of these lengths for $\xi \in \mathcal{C}_i$. 

THE DYNAMICS OF GENERIC KUPERBERG FLOWS 113
The function $S_i(\xi)$ is not continuous, but we note that the proof of Proposition 9.9 carries over to each of the surfaces $T_i$, so there exists a constant $\nu_\ast$ such that the set $S_{i,\xi} = \{s \mid \Phi_s(\xi) \in \mathcal{M} \cap T_i\}$ is syndetic for the constant $\nu_\ast$. Moreover, the constant $\nu_\ast$ can be chosen independent of $i$ and $\xi$. There is a similar notion in the estimation of the return time, $\nu_\ast$, which bounds the return time of a point in $T_i$ to the same transversal. The return point is contained in $\mathcal{C}_i = \mathcal{M} \cap T_i$ but not necessarily in the subset $\mathcal{C}_i$. However, Lemma 15.2 and Proposition 15.4 imply that there exists a uniform constant which is an upper bound on the length of time any orbit spends in a bubble. That is, the time required to flow across each of the internal notches as illustrated in Figures 25 and 26 has a uniform bound. Thus, replacing $\nu_\ast$ with a fixed multiple of itself, we may assume that $\nu_\ast$ is a syndetic constant for $S_{i,\xi} = \{s \mid \Phi_s(\xi) \in \mathcal{C}_i\}$ for each $1 \leq i \leq 5$.

Consider the annulus $A \subset \mathbb{W}$ and its image $\tau(A)$ in $\mathbb{K}$. For each $\theta \in \mathbb{S}^1$ consider the sets
\begin{align*}
\mathcal{R}_{\theta} &= \{\tau_r(\theta, z) \mid (r, \theta, z) \in \mathbb{W}', 2 \leq r \leq 3, -2 \leq z \leq 2\} \\
\mathcal{T}_{\theta} &= \{\tau_r(\theta, 0) \mid 2 \leq r \leq 3\}
\end{align*}
with $\mathcal{T}_{\theta} \subset \mathcal{R}_{\theta}$. Observe that for those values of $\theta$ for which all the points $(r, \theta, z)$ are not in $\mathcal{D}_i$ for $i = 1, 2$, $\mathcal{R}_{\theta}$ is a rectangle in $\mathbb{K}$. On $\mathcal{T}_{\theta}$ consider the set of points $\mathcal{C}_{\theta} = \mathcal{T}_{\theta} \cap \mathcal{M}_0$. This set contains two types of points: those that belong to a closed curve in $\mathcal{R}_{\theta} \cap \mathcal{M}_0$ that we denote by $\mathcal{C}_{\theta}$ and those that belong to an arc in $\mathcal{R}_{\theta} \cap \mathcal{M}_0$.

Consider the set $\mathcal{C}_{\theta} = \mathcal{C}_{\theta} - \mathcal{C}_{\theta}$ and its closure $\mathcal{C}_{\theta}$. Observe that $\mathcal{C}_{\theta} - \mathcal{C}_{\theta} = \mathcal{C}_{\theta}$. Let $\mathcal{A}_{\theta}$ be the union over $\theta$ of these Cantor sets $\mathcal{C}_{\theta}$. Observe that $\mathcal{A}_{\theta}$ contains the intersection of $\tau(A)$ with all the simples propellers in $\mathcal{M}_0$.

Let $\mathcal{M}_{i,\xi} \subset \mathcal{M} \cap T_i$ be the path components that contain a point in $\mathcal{C}_i$ for $1 \leq i \leq 5$, and define $W = \mathcal{M}_{i,\xi} \cup \cdots \cup \mathcal{M}_{i,\xi} \cup \mathcal{A}_{\theta} = \mathcal{M}_{i,\xi} \cup \cdots \cup \mathcal{M}_{i,\xi} \cup \mathcal{A}_{\theta}$ be the union of these closed sectors in $\mathbb{K}$. For each $i$ and for $x \in \mathcal{M}_{i,\xi}$, define $T_i^\pm(x)$, which is the forward and backwards “return time” to $W$ for the flow $\Phi_\ast$:
\begin{equation}
T_i^+(x) = \inf \{s > 0 \mid \Phi_s(x) \in W\}, \quad T_i^-(x) = \sup \{s < 0 \mid \Phi_s(x) \in W\}.
\end{equation}

For $\xi \in \mathcal{C}_i$ we have that $|T_i^+(\gamma_\xi(s))| < \nu_\ast$ uniformly. The values of these functions are not necessarily continuous in the variables $\xi$ and $s$. The discontinuities may arise, for example, when the endpoint of the flow segment starting at $\gamma_\xi(s)$ jumps from a section $T_j$ to the annulus $A$.

For each $1 \leq i \leq 5$, define the subsets of $\mathcal{C}_i^+ \times [-L_i, L_i] \times [-\nu_\ast, \nu_\ast]$,
\begin{align*}
D_{i,1}^- &= \{((\xi, s, t) \mid \xi \in \mathcal{C}_i^+, -S_i(\xi) \leq s \leq 0, T_i^-(\gamma_\xi(s)) \leq t \leq T_i^+(\gamma_\xi(s))\} \\
D_{i,2}^- &= \{((\xi, s, t) \mid \xi \in \mathcal{C}_i^+, 0 \leq s \leq S_i(\xi), T_i^+(\gamma_\xi(s)) \leq t \leq T_i^+(\gamma_\xi(s))\}.
\end{align*}
Let $\epsilon_\ast > 0$ be sufficiently small so that the $\epsilon_\ast$-neighborhood of $W$ in $\mathbb{K}$ is disjoint from the surfaces $E_i$ and $S_j$ for $1 \leq i, j \leq 5$ as defined in \[9\]. Then for each $1 \leq i \leq 5$, also define
\begin{align*}
D_{i,1}^+ &= \{((\xi, s, t) \mid \xi \in \mathcal{C}_i^+, -S_i(\xi) \leq s \leq 0, T_i^-(\gamma_\xi(s)) - \epsilon_\ast \leq t \leq T_i^+(\gamma_\xi(s)) + \epsilon_\ast\} \\
D_{i,2}^+ &= \{((\xi, s, t) \mid \xi \in \mathcal{C}_i^+, 0 \leq s \leq S_i(\xi), T_i^+(\gamma_\xi(s)) - \epsilon_\ast \leq t \leq T_i^+(\gamma_\xi(s)) + \epsilon_\ast\}.
\end{align*}

Introduce the continuous maps:
\begin{align*}
\varphi_{i,1}: D_{i,1}^+ &\to \mathcal{M}, \quad \varphi_{i,1}(\xi, s, t) = \Phi_\ast(\gamma_\xi(s)) \\
\varphi_{i,2}: D_{i,2}^+ &\to \mathcal{M}, \quad \varphi_{i,2}(\xi, s, t) = \Phi_\ast(\gamma_\xi(s)).
\end{align*}

**Proposition 19.6.** For each $1 \leq i \leq 5$ and $j = 1, 2$, the map $\varphi_{i,j}: D_{i,j}^+ \to \mathcal{M}$ is one-to-one. Moreover, we have
\[\mathcal{M} = \bigcup_{1 \leq i \leq 4} \{\varphi_{i,1}(\varphi_{i,1}) \cup \varphi_{i,2}(\varphi_{i,2})\}.
\]
Proof. Suppose that \((\xi, s, t) \neq (\xi', s', t') \in D^{\sigma}_{\xi, j}\) satisfy \(\varphi_{i,j}(\xi, s, t) = \varphi_{i,j}(\xi', s', t')\) for some \(i, j\). Let \(x = \gamma_{\xi}(s)\) and \(x' = \gamma_{\xi'}(s')\) then \(x' = \Phi_{s'}(\varphi_{i,j}(\xi, s, t)) = \Phi_{s'}(\Phi_t(x)) = \Phi_{t'-t}(x)\). Assume without loss of generality that \(t - t' > 0\). Then there is a \(K\)-orbit segment \(\sigma\) from \(x \in T_1\) to \(x' \in T_i\) whose interior intersects at most once \(W\). Let \(x_1, x_2, \ldots\) be the transition points in the forward \(K\)-orbit of \(x\). Observe that \(\sigma\) must contain at least one transition point.

Assume first that \(\sigma \cap A_\xi\) is empty. By the choices of \(T_i\), we have that:

1. \(x \in T_1 \cap \{z < 0\}\) then \([x, x_1]_{K}\) intersects \(T_2 \cap \{z < 0\}\).
2. \(x \in T_2 \cap \{z < 0\}\) then either \([x, x_1]_{K}\) intersects \(T_3 \cap \{z < 0\}\) or \(x_1\) is in \(E_1\).
3. \(x \in T_3 \cap \{z < 0\}\) then \([x, x_1]_{K}\) intersects \(T_4 \cap \{z < 0\}\).
4. \(x \in T_4 \cap \{z < 0\}\) then \([x, x_1]_{K}\) intersects \(T_5 \cap \{z < 0\}\).
5. \(x \in T_5 \cap \{z < 0\}\) then \([x, x_1]_{K}\) intersects \(T_1 \cap \{z < 0\}\).
6. \(x \in T_1 \cap \{z > 0\}\) then \([x, x_1]_{K}\) intersects \(T_3 \cap \{z > 0\}\).
7. \(x \in T_2 \cap \{z > 0\}\) then either \([x, x_1]_{K}\) intersects \(T_1 \cap \{z > 0\}\) or \(x_1\) is in \(E_2\).
8. \(x \in T_3 \cap \{z > 0\}\) then \([x, x_1]_{K}\) intersects \(T_2 \cap \{z > 0\}\).
9. \(x \in T_4 \cap \{z > 0\}\) then \([x, x_1]_{K}\) intersects \(T_3 \cap \{z > 0\}\) or \(x_1\) is in \(S_2\).
10. \(x \in T_5 \cap \{z > 0\}\) then either \([x, x_1]_{K}\) intersects \(T_4 \cap \{z > 0\}\) or \(x_1\) is in \(S_1\).

If \(\sigma\) intersects \(W\) only at its endpoints, in cases (1), (3), (4), (5), (6) and (8) we obtain a contradiction. We next analyze the other four possible cases.

2. Assume that \(x \in T_2 \cap \{z < 0\}\), then \(x_1 \in E_1\). From \(x_1\), the orbit segment \(\sigma\) either continues to a point \(y_1 \in T_3\) or it flows to \(x_2 \in S_1\) before intersecting \(W\), with \(x_1 \equiv x_2\). In the first case, if \(y_1 \in M_\xi\), we obtain a contradiction. If not, \(r(x_1) > 2\) and \(\sigma\) contains the point \(\pi_1 \in S_1\) such that \(x_1 \equiv \pi_1\) (this is the case when \(\sigma\) contains a segment of \(K\)-orbit in a bubble). Thus there exists \(k \geq 2\) such that \(x_k \in S_1\) with \(x_1 \equiv x_k\). From \(x_k\) the segment \(\sigma\) continues and hits \(M_\xi \subset T_3\), giving us a contradiction. Observe that in the second case we obtain the same contradiction with \(k = 2\).

7. If \(x \in T_2 \cap \{z > 0\}\) then \(x_1 \in E_2\). From \(x_1\), the orbit segment \(\sigma\) either continues to a point \(y_1 \in T_4\) or it flows to \(x_2 \in S_2\) before intersecting \(W\), with \(x_1 \equiv x_2\). In the first case, either \(y_1 \in M_\xi\) and we obtain a contradiction, or there exists \(k \geq 2\) such that \(x_k \in S_2\) with \(x_1 \equiv x_k\) and \([x_1, x_k]_{K} \cap W = \emptyset\). From \(x_k\) the segment \(\sigma\) continues and hits \(M_\xi \subset T_1\), giving us a contradiction. Observe that in the second case we obtain the same contradiction.

9. If \(x \in T_4 \cap \{z > 0\}\) then \(x_1 \in S_2\). From \(x_1\), the orbit segment \(\sigma\) continues to a point \(y_1 \in T_1\). Since \(x_1\) is a secondary exit point, \(y_1 \in M_\xi\), a contradiction.

10. If \(x \in T_5 \cap \{z > 0\}\) then \(x_1 \in S_2\). From \(x_1\), the orbit segment \(\sigma\) continues to a point \(y_1 \in T_3\). Since \(x_1\) is a secondary exit point, \(y_1 \in M_\xi\), a contradiction.

We are left with the case where the interior of \(\sigma\) intersects \(W\), that we separate in two situations, first when the intersection point is in \(W - A_\xi\) and second when it is in \(A_\xi\). In the first situation, concatenating the cases above, we conclude that there is no \(K\)-orbit segment with both endpoints in one of transversals and intersecting \(W - A_\xi\).

In the case where \(\sigma \cap A_\xi \neq \emptyset\), the only possibility for such a segment is to flow from \(x\) to a transition point \(x_1\). If \([x_1, x_2]_K\) does not intersects \(W\), then \(x_1 \equiv x_2\) and we can replace it with a short cut. Then, \(x \in T_2\) and, by (2) and (7) above, the arc \([x_2, x_3]_K\) intersects \(W - A_\xi\). Thus the first intersection point of \(\sigma\) with \(W\) is either in \(T_1\) or \(T_3\). A contradiction.

Hence, \([x_1, x_2]_K\) must intersect \(A_\xi\). Let \(y\) be the intersection point. If \(x_1\) is a secondary entry point, then \(x_1 \equiv x_2\), \(x \in T_2\) and \(x'\) is either in \(T_1\) or \(T_3\). If \(x_1\) is a secondary exit point, then \(x \in T_4 \cap \{z > 0\}\) or \(x \in T_5 \cap \{z > 0\}\). In the first case, \(x_1 \in S_2\) and thus has \(z\)-coordinate positive. Case (9) above implies that its orbit intersects \(W - A_\xi\) before intersecting \(A_\xi\). In the second case, \(x_1 \in S_1\) and by assumption its forward orbit intersects \(A_\xi\) before intersecting the transversal \(T_3\). Then it flows in the negative \(\theta\)-direction to the transversal \(T_2\), and since \(x_1\) is a secondary exit point, the last intersection point belongs to \(M_\xi\). The last contradiction we needed.
Thus, the maps $\varphi_{i,j}$ are homeomorphisms. By definition they cover $\mathcal{M}$. \hfill \Box

20. Entropy of the Flow

A celebrated theorem of Katok [24] on the entropy for C^2-flows on compact 3-manifolds implies that the topological entropy of the Kuperberg flow $\Phi_t$ is zero. In this section, we give a geometric proof of this conclusion, based on an analysis of the dynamics of the flow $\Phi_t$ restricted to the closed invariant set $\mathcal{M}$. The key idea is to relate the flow entropy to another type of entropy invariant, which is derived from the pseudogroup dynamics for $G_K$ acting on the rectangle $R_0$.

We first prove, in Proposition 20.9, that the entropy of the flow vanishes if the entropy of the return map $\hat{\Phi}$ vanishes. Then in Proposition 20.13 we relate the entropy of $\hat{\Phi}$ to the entropy of the pseudogroup $\hat{G}_K$, proving that they are proportional. Finally, in Theorem 20.14 we show that the entropy $h_{GLW}(\hat{G}_K^\star|\mathcal{M}_{R_0})$ of $\hat{G}_K^\star$ vanishes. The study of the various pseudogroup entropies associated to the flow $\Phi$ reveals the geometrical principles behind the vanishing of its entropy, and provides further insights into the dynamics of this flow.

We define the entropy of the flow $\Phi_t$ using a variation of the Bowen formulation of topological entropy [6] for a flow on a compact metric space $(X, d_X)$. The definition we adopt is symmetric in the role of the time variable $t$. Two points $p, q \in X$ are said to be $(\varphi_t, T, \epsilon)$-separated if

$$d_X(\varphi_t(p), \varphi_t(q)) > \epsilon \quad \text{for some} \quad -T \leq t \leq T.$$  

A set $E \subset X$ is $(\varphi_t, T, \epsilon)$-separated if all pairs of distinct points in $E$ are $(\varphi_t, T, \epsilon)$-separated. Let $s(\varphi_t, T, \epsilon)$ be the maximal cardinality of a $(\varphi_t, T, \epsilon)$-separated set in $X$. Then the topological entropy is defined by

$$(128) \quad h_{top}(\varphi_t) = \frac{1}{2} \cdot \lim_{\epsilon \to 0} \limsup_{T \to \infty} \frac{1}{T} \log(s(\varphi_t, T, \epsilon)).$$

Moreover, for a compact space $X$, the entropy $h_{top}(\varphi_t)$ is independent of the choice of metric $d_X$.

A relative form of the topological entropy for a flow $\varphi_t$ can be defined for any subset $Y \subset X$, by requiring that the collection of distinct $(\varphi_t, T, \epsilon)$-separated points used in the definition (128) be contained in $Y$. The restricted topological entropy $h_{top}(\varphi_t|Y)$ is bounded above by $h_{top}(\varphi_t)$.

Katok proved in [24] Corollary 4.4 that for a C^2-diffeomorphism of a compact surface, or for a C^2-flow on a compact 3-manifold, its topological entropy is bounded above by the exponent of the rate of growth of its periodic orbits. In particular, Katok’s result implies:

**THEOREM 20.1 (Katok 1980).** Let $\varphi_t: M \to M$ be a C^2-flow on a compact 3-manifold. Suppose that $\varphi_t$ has no periodic orbits, then $h_{top}(\varphi_t|\mathcal{M}) = 0$.

Suppose that $\varphi_t$ is an aperiodic flow obtained by inserting the Kuperberg flow $\Phi_t$ on $\mathbb{K}$ into a flow box for some flow on a compact 3-manifold. Then $h_{top}(\varphi_t) = 0$ by Theorem 20.1, and thus we have $h_{top}(\varphi_t|\mathcal{M}) = 0$ for the flow $\varphi_t$ restricted to the invariant set $\mathcal{M}$. By construction, the flows $\varphi_t$ and $\Phi_t$ agree on $\mathcal{M}$, so that $h_{top}(\Phi_t|\mathcal{M}) = h_{top}(\varphi_t|\mathcal{M}) = 0$. That is, the topological entropy vanishes for the restriction of the flow $\Phi_t$ to the space $\mathcal{M}$ with the induced metric. In this section, we give a proof that $h_{top}(\Phi_t|\mathcal{M}) = 0$ based on the dynamics of the restricted flow $\Phi_t: \mathcal{M} \to \mathcal{M}$ and the geometry of the invariant set $\mathcal{M}$.

The idea of our approach to the calculation of $h_{top}(\Phi_t|\mathcal{M})$, is to consider the return map $\hat{\Phi}$ on the rectangle $R_0$, and relate the entropy of the flow $\Phi_t$ restricted to $\mathcal{M}$ with the entropy $h_{top}(\hat{\Phi}|\mathcal{M}_{R_0})$ for $\hat{\Phi}$ restricted to its invariant set $\mathcal{M}_{R_0} = \mathcal{M} \cap R_0$. It is standard to relate the entropy of the flow with the entropy of an induced return map to a section to the flow, assuming that the flow is everywhere transverse to the section. However, the flow $\Phi_t$ is not everywhere transverse to $R_0$ as it is tangent to $R_0$ along its center line $T = \{z = 0\} \cap R_0$. As discussed below, these tangencies result in discontinuities for the induced map $\hat{\Phi}$, which make the relationship between $h_{top}(\Phi_t|\mathcal{M})$ and the entropy $h_{top}(\hat{\Phi}|\mathcal{M}_{R_0})$ more subtle. We subsequently relate
the entropy $h_{\text{top}}(\hat{\Phi}|\mathcal{M}_{\mathbb{R}^n})$ with the entropy $h_{\text{GLW}}(\mathcal{G}_k^*|\mathcal{M}_{\mathbb{R}^n})$ for the pseudo\-group $\mathcal{G}_k^*$ defined in Definition 9.8 and then show that $h_{\text{GLW}}(\mathcal{G}_k^*|\mathcal{M}_{\mathbb{R}^n}) = 0$.

We first recall the definition of entropy for pseudo\-groups as introduced by Ghys, Langevin and Walczak in [16] Section 2. Let $(X,d_X)$ be a complete metric space, and $\mathcal{G}_X^{(1)} = \{\varphi_0 = \text{Id}, \varphi_1, \varphi_1^{-1}, \ldots, \varphi_k, \varphi_k^{-1}\}$ be a set of local homeomorphisms of $X$, with their inverses. Then, for each $1 \leq i \leq k$ there are open sets $U_i, V_i \subset X$ such that $\varphi_i: U_i \rightarrow V_i$ is a homeomorphism. We require that each map $\varphi_i$ admits an extension to a homeomorphism $\bar{\varphi}_i$ of an open neighborhood of the closure $\overline{U}_i$ of the domain in $X$. Let $\mathcal{G}_X$ denote the pseudogroup generated by the collection of maps $\mathcal{G}_X^{(1)}$, so that the axioms of Definition 9.3 are satisfied. Let $\mathcal{G}_X^* \subset \mathcal{G}_X$ denote the pseudo\-group generated by the compositions of maps in $\mathcal{G}_X^{(1)}$, so that $\mathcal{G}_X$ satisfies conditions (1) to (4) of Definition 9.3, but not necessarily the condition (5). Let $\mathcal{G}_X^{(n)} \subset \mathcal{G}_X^*$ be the collection of maps defined by the restrictions of compositions of at most $n$ elements of $\mathcal{G}_X^{(1)}$.

For $\epsilon > 0$, say that $x, y \in X$ are $(\mathcal{G}_X^*, n, \epsilon)$-separated if there exists $\varphi \in \mathcal{G}_X^{(n)}$ such that $x, y$ are in the domain of $\varphi$ and $d_X(\varphi(x), \varphi(y)) > \epsilon$. In particular, if the identity map is the only element of $\mathcal{G}_X^{(n)}$ which contains both $x$ and $y$ in its domain, then they are $(\mathcal{G}_X^*, n, \epsilon)$-separated if and only if $d_X(x, y) > \epsilon$.

A finite set $E \subset X$ is said to be $(\mathcal{G}_X^*, n, \epsilon)$-separated if each distinct pair $x, y \in E$ is $(\mathcal{G}_X^*, n, \epsilon)$-separated. Let $s(\mathcal{G}_X^*, n, \epsilon)$ be the maximal cardinality of a $(\mathcal{G}_X^*, n, \epsilon)$-separated subset of $X$.

Define the entropy of $\mathcal{G}_X^*$ by:

\[
n(129) \quad h_{\text{GLW}}(\mathcal{G}_X^*) = \lim_{\epsilon \to 0} \left\{ \limsup_{n \to \infty} \frac{1}{n} \ln(s(\mathcal{G}_X^*, n, \epsilon)) \right\}.
\]

The property $0 < h_{\text{GLW}}(\mathcal{G}_X^*) < \infty$ is independent of the choice of metric on $X$. Note that the denominator in the expression (129) is the word length $n$. Thus, $h_{\text{GLW}}(\mathcal{G}_X^*)$ differs from other definitions of entropy for group actions which scale by volume growth, rather than length.

A key observation in [16] is that if the generators $\mathcal{G}_X^{(1)}$ are the restrictions of $C^1$-diffeomorphisms defined on the compact closures of open subsets of a manifold $M$, then $h_{\text{GLW}}(\mathcal{G}_X^*) < \infty$. A discussion of some of the dynamical implications of $h_{\text{GLW}}(\mathcal{G}_X^*) > 0$ for $C^1$-pseudogroups is given in [16, 18, 21, 49].

Given a subset $Y \subset X$, we can restrict consideration to subsets $E \subset Y$ which are $(\mathcal{G}_X^*, n, \epsilon)$-separated. Let $s(\mathcal{G}_X^*, Y, n, \epsilon)$ be the maximal cardinality of such an $(\mathcal{G}_X^*, n, \epsilon)$-separated subset of $Y$. Define the restricted entropy by

\[
n(130) \quad h_{\text{GLW}}(\mathcal{G}_X^*|Y) = \lim_{\epsilon \to 0} \left\{ \limsup_{n \to \infty} \frac{1}{n} \ln(s(\mathcal{G}_X^*, Y, n, \epsilon)) \right\} \leq h_{\text{GLW}}(\mathcal{G}_X^*) .
\]

Before considering the entropy invariants associated to the return map $\hat{\Phi}$, we consider the points of discontinuity for its powers $\hat{\Phi}^n$, and use this to give a description of the domains of continuity of the maps $\hat{\Phi}^n$. We restrict to the region $\mathbb{R}_0 \cap \{r \geq 2\}$ which contains the set $\mathcal{M}_{\mathbb{R}_0}$. In Section 9 the continuity properties for the induced return map $\hat{\Psi}$ of the Wilson flow were analyzed, which resulted in the description of its domains of continuity in (30). The analysis of the powers of the map $\hat{\Phi}$ extends this analysis.

Recall that by Condition (K3) in Section 3, the compact annular region $\mathcal{A}(2) = \{(r, \theta, 0) \mid r \geq 2\} \subset \mathcal{A}$ is disjoint from the images of the insertions $\sigma_i$ for $i = 1, 2$, thus the vector fields $\mathcal{W}$ and $\mathcal{K}$ agree on an open neighborhood of $\mathcal{A}(2)$ and so the flows $\Psi_t$ and $\Phi_t$ agree near $\mathcal{A}(2)$ for $t$ near to 0.

Consider a point $\xi_0 \in \text{Dom}(\hat{\Phi}) \cap \{r \geq 2\}$ with $\xi_1 = \hat{\Phi}(\xi_0)$. Then there exists a $\mathcal{K}$-orbit segment $[\xi_0, \xi_1]_\mathcal{K}$ which intersects $\mathbb{R}_0$ only in its endpoints. If the $\mathcal{K}$-flow $\Phi_t(\xi_0)$ intersects $\mathbb{R}_0$ transversally at $\xi_1$, then there is an open neighborhood in $\mathbb{R}_0$ of $\xi_0$ consisting of points whose flow is also transverse to $\mathbb{R}_0$ near $\xi_1$, and thus $\hat{\Phi}$ is continuous at $\xi_0$. On the other hand, if the $\mathcal{K}$-flow $\Phi_t(\xi_0)$ intersects $\mathbb{R}_0$ tangentially at $\xi_1$, then in every open neighborhood of $\xi_0$ there is some point whose flow does not intersect $\mathbb{R}_0$ near $\xi_1$, and the map $\hat{\Phi}$ will be discontinuous at $\xi_0$. Thus, $\xi_0$ is a point of discontinuity for $\hat{\Phi}$ precisely when it is contained in the inverse
image under $\hat{\Phi}$ of the center line $T = \{ x \in \mathbb{R}_0 \mid z(x) = 0 \}$. That is, the set of discontinuities for $\hat{\Phi}$ is the set $\hat{\Phi}^{-1}(T)$. Similarly, the set of discontinuities for the inverse map $\hat{\Phi}^{-1}$ is the set $\hat{\Phi}(T)$.

These remarks for $\hat{\Phi}$ generalize to its powers as follows. Let $n > 1$ and $\xi_0 \in \text{Dom}(\hat{\Phi}^n)$, then set $\xi_\ell = \hat{\Phi}^\ell(\xi_0)$ for $1 \leq \ell \leq n$. If the $K$-orbit segment $[\xi_0, \xi_n]$ intersects $\mathbb{R}_0$ transversally at each point $\xi_\ell$ then there is an open neighborhood of $\xi_0$ in $\mathbb{R}_0$ consisting of points whose flow is also transverse to $\mathbb{R}_0$, and thus $\hat{\Phi}^n$ is continuous at $\xi_0$. On the other hand, if the $K$-orbit segment $[\xi_0, \xi_n]$ intersects $\mathbb{R}_0$ tangentially at some point $\xi_\ell$, that is $\xi_\ell \in T \subset \mathbb{R}_0$, then in every open neighborhood of $\xi_0$ there is some point whose flow does not intersects $\mathbb{R}_0$ near $\xi_\ell$, and thus $\xi_0$ is a point of discontinuity for $\hat{\Phi}^n$. For each integer $\ell$, introduce the subset of $\text{Dom}(\hat{\Phi}^\ell)$,

\[(131) \quad L_\ell = \hat{\Phi}^{-\ell}(T) = \hat{\Phi}^{-\ell}(T \cap \text{Dom}(\hat{\Phi}^{-\ell})) .\]

The above discussion implies that for $n \geq 1$, $\xi \in \text{Dom}(\hat{\Phi}^n)$ is a point of discontinuity for $\hat{\Phi}^n$ precisely when there exists $1 \leq \ell \leq n$ such that $\xi \in L_\ell$. The analogous statement also holds for $\xi \in \text{Dom}(\hat{\Phi}^{-n})$ with $n > 0$ and $-n \leq \ell < 0$. For $n \geq 1$, define

\[(132) \quad D^{(n)}(\hat{\Phi}) = \bigcap_{-n \leq \ell \leq n} \left\{ \text{Dom}(\hat{\Phi}^\ell) - L_\ell \right\} \cap \{ r \geq 2 \} .\]

Let $U \subset D^{(n)}(\hat{\Phi})$ be a connected component, then $\hat{\Phi}^\ell|U$ is continuous for all $-n \leq \ell \leq n$. Thus, we are interested in the finite collection of domains of continuity,

\[(133) \quad D^{(n)}_{\text{M}R_0}(\hat{\Phi}) = \{ U \subset D^{(n)}(\hat{\Phi}) \mid U \text{ is a connected component of } D^{(n)}(\hat{\Phi}) \text{ such that } U \cap \text{M}R_0 \neq \emptyset \} .\]

Corollary 9.14 implies that $\text{M}R_0 \subset \text{Dom}(\hat{\Phi}^n) \cap \text{Dom}(\hat{\Phi}^{-n})$ for all $n$. For $U \in D^{(n)}_{\text{M}R_0}(\hat{\Phi})$, let $\overline{U} \subset \mathbb{R}_0$ denote its closure, then we have:

**Lemma 20.2.** For each $n \geq 1$, $\text{M}R_0 \subset \bigcup \{ \overline{U} \mid U \in D^{(n)}_{\text{M}R_0}(\hat{\Phi}) \} .$

The collection $D^{(n)}_{\text{M}R_0}(\hat{\Phi})$ thus gives a decomposition of $\hat{\Phi}$ into sets on which the function has nice regularity properties. The number of sets in these partitions is an important property of the flow $\Phi_t$.

**Definition 20.3.** The complexity function of $\hat{\Phi}$ is defined by $C_{\Phi}(n) = \# D^{(n)}_{\text{M}R_0}(\hat{\Phi})$. That is, for $n \geq 1$, $C_{\Phi}(n)$ is the number of connected components of $D^{(n)}(\hat{\Phi})$.

We develop a geometric interpretation of the sets $L_\ell$ and $U \in D^{(n)}(\hat{\Phi})$, in terms of the flow $\Phi_t$, restricted to the space $\mathbb{M}_0$. We use this to relate the function $C_{\Phi}(n)$ to the function $\# \mathcal{M}(n)$, where the collection $\mathcal{M}(n) \subset \mathcal{G}^{(n)}_K$ was defined in Proposition 14.3.

We require some preliminary observations. We first obtain an estimate relating the exponent $\ell$ and the time $T$, for the maps $\hat{\Phi}^\ell$ and the flow $\Phi_T$ restricted to $\mathbb{M}$. It is straightforward to obtain such an estimate for a complete transversal to the flow $\Phi_t$ with return times bounded away from zero, but the estimate is more subtle for the return map $\hat{\Phi}$.

**Lemma 20.4.** There exist $L_\Phi > 0$ so that for $x \in \mathbb{M}_0$, and $T > 0$ such that $\Phi_T(x) \in \mathbb{M}_0$, and $n_x > 0$ for which $\hat{\Phi}^{2n_x}(x) = \Phi_T(x)$, then $0 < L_\Phi n_x \leq T$.

**Proof.** We use the properties of the return map $\hat{\Phi}$ established in Section 9.

Let $x \in \mathbb{M}_0$ with $r(x) \geq 2$, $z(x) < 0$ and $z(\hat{\Phi}(x)) < 0$. If the $K$-orbit of $x$ does not intersect an insertion region $L_i^-$ it must complete a revolution around the core cylinder $C$ before returning to $\mathbb{R}_0$, hence the segment $[x, \hat{\Phi}(x)]_K$ has length bounded below by $L'_\Phi = 4\pi$. If the $K$-orbit of $x$ does intersect an insertion region $L_i^-$ then the segment $[x, \hat{\Phi}(x)]_K$ has length at least $L''_\Phi$ for some $L''_\Phi > 0$. Let $L_\Phi = \min\{L'_\Phi, L''_\Phi\}$.

In the case where $x \in \mathbb{M}_0$, with $z(x) > 0$ and $z(\hat{\Phi}(x)) > 0$, then the segment $[x, \hat{\Phi}(x)]_K$ traverses $K$ in the clockwise direction, but is otherwise analogous to the case above. We assume that the estimates $L'_\Phi$ and $L''_\Phi$ also apply in this case.
In the case where \( x \in \mathcal{M}_{R_0} \) with \( z(x) \leq 0 \) and \( z(\hat{\Phi}(x)) \geq 0 \), then the flow \( \Phi_t(x) \) crosses the annulus \( \{ z = 0 \} \).

In particular, \( \hat{\Phi}(x) = \psi(x) \) for the map \( \psi \) of the pseudogroup \( \mathcal{G}_K \). Recall that the action of \( \psi \) was described in Lemma 13.6 and we observe that the length of the segment \( [x, \hat{\Phi}(x)]_\xi \) need not have a positive lower bound. But this segment must be preceded and followed by a segment of the above two types. It follows that the composition \( \hat{\Phi} \circ \Phi \) applied to \( x \in \mathcal{M}_{R_0} \) is realized by a \( K \)-orbit segment of length at least \( L_{\Phi} \), for any \( x \in \mathcal{M}_{R_0} \).

It follows that \( [x, \hat{\Phi}^{2n_\xi}(x)]_\xi \) has length at least \( L_{\Phi} \cdot n_\xi \).

Recall that by Propositions 15.1 and 15.4, the constant \( r_B > 2 \), introduced in Definition 78, provides a lower bound for the radius of points in bubbles of the first type. Also, Lemma 18.7 provides a constant \( r_B > 2 \) for which bubbles of the second type do not arise. Finally, \( r_e \) is the exceptional radius defined in 133. Let \( r_u = \min\{r_B, r_B, r_e\} \), so that \( 2 < r_u \leq r_e \). Observe that the techniques in the proof of Proposition 9.16 apply for any value of the radius upper bound which is less than \( r_e \). In particular, we conclude the following:

**PROPOSITION 20.5.** Let \( \xi \in R_0 \) have infinite orbit for the flow \( \Phi_1 \) with \( r(\xi) < r_u \) and \( \rho_\xi(t) \geq 2 \) for all \( t \). Then the set \( S^*(\xi, r_u) = \{ s \mid \Phi_s(\xi) \in \mathcal{G}_K^s(\xi) \subset R_0 ~,~ r(\Phi_s(\xi)) < r_u \} \) is syndetic in \( R \) for a constant \( \nu_u^* \) which is independent of \( \xi \).

**COROLLARY 20.6.** Let \( \xi \in \mathcal{M}_{R_0} = \mathcal{M} \cap R_0 \). Then \( S^*(\xi, r_u) = \{ s \mid \Phi_s(\xi) \in \mathcal{G}_K^s(\xi) \subset R_0 ~,~ r(\Phi_s(\xi)) < r_u \} \) is syndetic in \( R \) for the constant \( \nu_u^* \).

**Proof.** Theorem 8.2 implies that the \( \Phi_t \)-orbit of \( \xi \) contains points arbitrarily close to the special point \( \omega_1 \in R_0 \), and thus there exists \( t \) such that \( 2 \leq r(\Phi_t(\xi)) < r_u \). The claim then follows from Proposition 20.5.

**COROLLARY 20.7.** Let \( M_0 > 0 \) be the greatest integer with \( M_0 < 2\nu_u^* \). For each \( x \in \mathcal{M}_{R_0} \) there exists \( 0 < l_x^t, l_x^s \leq M_0 \) such that \( r(\hat{\Phi}^{l_x^t}(x)) < r_u \) and \( r(\hat{\Phi}^{-l_x^s}(x)) < r_u \).

**Proof.** This follows from Lemma 20.4 and Corollary 20.6.

We next characterize the discontinuities of \( \hat{\Phi}^n \) on \( \mathcal{U} \), for \( U \in D^{(n)}(\hat{\Phi}) \). We first reduce this problem to a “standard form”. Recall from 64 that the interval \( I_0 = R \cap R_0 \) is the closed vertical segment whose \( \Phi_t \)-flow generates \( \mathcal{M}_0 \), and the intersection of \( \mathcal{M}_0 \) with \( R_0 \) yields the connected components of \( \mathcal{M}_{R_0} \). Also, the \( \Phi_t \)-flows of the closed vertical segments \( N_0 = J_0 \cup I_0 \subset R_0 \) and \( M_0 = I_0 \cup K_0 \subset R_0 \) generate the double propellers discussed in Section 13. The \( \Phi_t \)-flows of \( N_0 \) and \( I_0 \) generate families of nested double propellers, whose intersections with \( R_0 \) are the topological circles illustrated in Figures 31, 32 and 10. By the nesting properties of the double propellers, the discontinuities for \( \hat{\Phi}^n \) restricted to \( \mathcal{M}_{R_0} \) are determined by those for \( \hat{\Phi}^n \) restricted to \( I_0 \).

Suppose that \( x \in I_0 \) is a point of continuity for \( \hat{\Phi}^n \) with \( n \geq 1 \), so the restriction \( \hat{\Phi}^n \) to \( I_0 \) is continuous in an open neighborhood of \( x \). Let \( x', x'' \in I_0 \) be such that the open connected segment \( (x', x'') \subset I_0 \) is the maximal open subset of \( I_0 \) containing \( x \) such that the restriction \( \hat{\Phi}^n|(x', x'') \) is continuous. Set \( J(x, 0) = (x', x'') \). Then for each \( z \in J(x, 0) \) and \( w = \hat{\Phi}^n(z) \), the \( K \)-orbit segment \( [z, w]_K \) intersects \( R_0 \) transversally, while for the endpoints \( \{ x', x'' \} \), the \( K \)-orbit segments \( [x', \hat{\Phi}^n(x')]_K \) and \( [x'', \hat{\Phi}^n(x'')]_K \) must each contain a point of tangency with \( I \). The collection of such points of tangency for the flow \( \Phi_t \) partition \( I_0 \) into maximal subintervals on which the restriction of \( \hat{\Phi}^n \) is continuous.

We develop an estimate on the number of intervals of continuity for \( \hat{\Phi}^n \) in \( I_0 \), where we consider the case \( n > 0 \) first. Let \( x \in I_0 \) be a point of continuity. As \( r(x) = 2 \), by Corollary 20.7 there exists an infinite sequence \( \{ 0 < l_1 < l_2 < \cdots \} \) with \( (l_{i+1} - l_i) < M_0 \) for all \( i \geq 1 \), such that for \( x_1 = \hat{\Phi}^{l_1}(x) \) we have \( r(x_1) < r_u \).

Set \( I(x, 0) = I_0 \), and for \( i > 0 \) let \( I(x, i) \subset \mathcal{M}_0 \cap R_0 \) denote the maximal connected component containing \( x_i \). Then \( I(x, i) \) is a simple arc by the choice of \( r_u \). In particular, the endpoints of \( I(x, i) \) are contained in the boundary of \( \mathcal{M}_0 \). Let \( p_1^0(I(x, i)) \) denote the endpoint of \( I(x, i) \) in the region \( \{ z < 0 \} \), and \( p_0^0(I(x, i)) \) denote the endpoint of \( I(x, i) \) in the region \( \{ z > 0 \} \). In particular, \( p_1^0(I(x, 0)) = \omega_1 \) and \( p_0^0(I(x, 0)) = \omega_2 \) are the special points defined in 27.

THE DYNAMICS OF GENERIC KUPERBERG FLOWS 119
For \( i > 0 \), denote \( J(x,i) = \Phi^i(\mathcal{J}(x,0)) \subset \mathcal{I}(x,i) \). Then \( \mathcal{J}(x,i) \) is an open subinterval, disjoint from the center line \( \mathcal{T} \). For each \( i \geq 0 \), if \( \mathcal{J}(x,i) \) lies below the line \( \mathcal{T} \), let \( \zeta_i = p^0_{\mathcal{T}}(\mathcal{I}(x,i)) \in \mathbb{R}_0 \) denote the lower endpoint of the interval \( \mathcal{I}(x,i) \). If \( \mathcal{J}(x,i) \) lies above the line \( \mathcal{T} \), then \( \zeta_i = p^0_{\mathcal{T}}(\mathcal{I}(x,i)) \in \mathbb{R}_0 \) denotes the upper endpoint of the interval \( \mathcal{I}(x,i) \). Then Proposition 20.5 implies that for each \( i \geq 1 \) and \( n_i = \ell_i - \ell_{i-1} \) the restriction

\[
\hat{\Phi}^{n_i} : \mathcal{J}(x,i - 1) \to \mathcal{J}(x,i)
\]
corresponds to a map \( \varphi(x,i) \in \mathcal{G}_K^{(n_i)} \) which maps \( \zeta_{i-1} \) to \( \zeta_i \). Let \( \Upsilon(x,i) = \varphi(x,i) \circ \cdots \circ \varphi(x,2) \circ \varphi(x,1) \in \mathcal{G}_K^{(\ell_i)} \).

We next give a geometric interpretation to the maps in \( \mathcal{G}_K^{(n_i)} \) defined by the actions (134), in terms of the action of \( \mathcal{G}_K \) on \( \mathcal{T}_\Phi \) defined in Section 14.

The intersection \( \mathcal{M}_0 \cap \mathcal{R}_0 \) consists of simple arcs arising from the intersections with propellers, as discussed in Section 12, and double arcs or ellipses which arise from the intersection of \( \mathcal{R}_0 \) with bubbles in \( \mathcal{M}_0 \) as discussed in Section 15. The simple arcs in the intersection of \( \mathcal{M}_0 \cap \mathcal{R}_0 \) correspond to transverse line segments to the propellers, as illustrated in Figure 36. The double arcs resulting from the intersections with bubbles are illustrated in Figure 31 but for simplicity are not pictured in Figure 36. In particular, each arc \( \mathcal{I}(x,i) \subset \mathcal{M}_0 \cap \mathcal{R}_0 \) is an arc transverse to the flow \( \Phi_t \) in \( \mathcal{M}_0 \).

For each (simple) propeller \( P_x \) or \( P_y \) attached in the level decomposition of \( \mathcal{M}_0 \), as described in Section 11, the intersections \( P_x \cap \mathcal{A} \) and \( P_y \cap \mathcal{A} \) form the center line segments of the propeller, as illustrated in Figure 36. The union of all these lines form the subset \( \mathcal{T}_\Phi \subset \mathcal{T}_\Phi = \mathcal{M}_0 \cap \mathcal{A} \), as defined in Section 14. The intersections of \( \mathcal{T}_\Phi \) with \( \mathcal{T} = \mathcal{R}_0 \cap \mathcal{A} \) are the vertices in the set \( \mathcal{T}_\Phi \), as illustrated in Figure 36.

For each \( i \geq 1 \), the map \( \varphi(x,i) \) induces a map \( \varphi(x,i) \) from the vertex of \( \mathcal{T}_\Phi \) defined by \( \mathcal{I}(x,i-1) \cap \mathcal{T} \) to the vertex defined by \( \mathcal{I}(x,i) \cap \mathcal{T} \). Thus the map \( \Upsilon(x,i) : \mathcal{J}(x,0) \to \mathcal{J}(x,i) \) maps an open set in the simple arc \( \mathcal{I}(x,0) \) to an open set in the simple arc \( \mathcal{I}(x,i) \). We have \( \ell_i = n_1 + \cdots + n_i \) hence \( \Upsilon(x,i) = \hat{\Phi}^{\ell_i} \big| \mathcal{J}(x,0) \), so that \( \mathcal{J}(x,0) \) is contained in the domain of \( \hat{\Phi}^{\ell_i} \big| \mathcal{I}(x,0) \).

We return to the problem of estimating the number of domains of continuity for \( \hat{\Phi}^{n_i} \big| \mathcal{I}(x,0) \). Let \( x \in \mathcal{I}(x,0) \) be a point of continuity, let the indices \( \ell_i \) be defined as above, then let \( n_i > 0 \) be the least index \( i \) such that \( \ell_{n_i} \geq n \). Note that \( i_n \leq n \), and Corollary 20.6 implies that \( \ell_{i_n} \leq n + M_u \).

By Proposition 14.3, \( \Upsilon(x,i_n) \) can be written in normal form \( \Upsilon(x,i_n) = \varphi^+ \circ \varphi^- \in \mathcal{G}_K^{(\ell_{i_n})} \), where appropriate subwords in \( \Upsilon(x,i_n) \) are replaced by shortcuts, or powers of the generator \( \psi \). The interval \( \mathcal{I}(x,i_n) \) is thus defined by the word \( \varphi^+ \circ \varphi^- \). Proposition 14.5 implies the number of normal forms possible for word length \( \ell_{i_n} \) is bounded by \( \# \mathcal{M}(\ell_{i_n}) \leq \# \mathcal{M}(n + M_u) \). By Corollary 14.6, the function \( \# \mathcal{M}(n + M_u) \) has subexponential growth as a function of \( n \). It follows that the total number of simple arcs in \( \mathcal{M}_0 \cap \mathcal{R}_0 \) which are in the images of the map \( \hat{\Phi}^{n_i} \big| \mathcal{I}(x,0) \) is bounded above by \( \# \mathcal{M}(n + M_u) \).

Let \( x \in \mathcal{I}(x,0) \) be a point of continuity, and continuing the notation as above, for \( y = \hat{\Phi}^{n_i}(x) \), the \( K \)-orbit segment \( [x,y]_K \) is transverse to \( \mathcal{R}_0 \) at every point of intersection, and the orbit contains a point in each of the sequence of simple arcs \( \{ \mathcal{I}(x,i) \} \mid 0 \leq i \leq i_n \} \).

By the choice of the sequence \( \{ \ell_i \} \), for each \( 1 \leq i \leq i_n \), the forward \( K \)-flow in \( \mathcal{M}_0 \) of the points in the interval \( \mathcal{J}(x,i - 1) \) to the interval \( \mathcal{J}(x,i) \) has length at most \( \nu_u \). Therefore, there is a uniform upper bound \( M_u \) on the number of points \( \xi \in \mathcal{J}(x,i - 1) \) for which the orbit segment \( [\xi, \hat{\Phi}^{\ell_i}(\xi)]_K \) is tangent to \( \mathcal{T} \).

Recall that \( \{ x', x'' \} \subset \mathcal{I}(x,0) \) are the boundary points of the interval \( \mathcal{J}(x,0) \subset \mathcal{I}(x,0) \), and the \( K \)-orbit segments \( [x', \hat{\Phi}^{n_i}(x')]_K \) and \( [x'', \hat{\Phi}^{n_i}(x'')]_K \) each contains a point of tangency with \( \mathcal{T} \), which must be one of the points of tangency for the \( \Phi_t \)-flow between \( \mathcal{J}(x,i - 1) \) and \( \mathcal{J}(x,i) \) for some \( 1 \leq i \leq i_n \). Thus, the number of possible points of tangency with \( \mathcal{R}_0 \) which can define the lower boundary point \( x' \) for \( \mathcal{J}(x,0) \) has an upper bound estimate \( i_n \cdot M_u \leq n \cdot M_u \), and similarly for the upper boundary \( x'' \).

Thus, if \( \mathcal{J} \subset \mathcal{I}(x,0) \) is a maximal domain of continuity for \( \hat{\Phi}^{n_i} \big| \mathcal{I}(x,0) \), then there exists a connected component \( \mathcal{I}(U,n) \subset \mathcal{M}_0 \cap \mathcal{R}_0 \) for which \( \hat{\Phi}^{n_i}(\mathcal{J}) \subset \mathcal{I}(U,n) \). The number of possible such domains is bounded above
by \( \#\mathcal{M}(n + M_0) \). Then the number of maximal connected intervals \( \mathcal{J} \subset I_0 \) for which \( \hat{\Phi}^n(\mathcal{J}) \subset \mathcal{I}(U, n) \) is bounded above by the number of possible endpoints for the domains \( \mathcal{J} \), which is bounded above by \( (n \cdot M'_2)^2 \). It follows that the number of domains of continuity for \( \hat{\Phi}^n \) restricted to \( I_0 \) has subexponential growth.

Similar considerations apply to the analysis of \( \hat{\Phi}^{-n}|I_0 \), so that the number of domains of continuity for the collection of maps \( \{ \hat{\Phi}^\ell|I_0 \mid -n \leq \ell \leq n \} \) is a function of subexponential growth in \( n \). We thus obtain:

**Proposition 20.8.** The function \( C_\Phi(n) \) has subexponential growth for a generic Kuperberg flow \( \Phi \).

We now return to the definition and calculation of the entropy invariants associated with \( \hat{\Phi} \). Recall from Section 9 that \( \mathcal{G}_K \) is the pseudogroup generated by \( \hat{\Phi} \) acting on \( X = R_0 \).

Let \( V_+ = \{ x \in \text{Dom}(\hat{\Phi}) \mid z(x) > 0 \} \), let \( V_- \) be the region of \( \text{Dom}(\hat{\Phi}) \) which lies below the curve \( \mathcal{L}_1 \) and let \( V_0 \) be the region between \( V_- \) and \( V_+ \). Then set

\[
\hat{\Phi}_- \equiv \hat{\Phi}|V_- \quad , \quad \hat{\Phi}_0 \equiv \hat{\Phi}|V_0 \quad , \quad \hat{\Phi}_+ = \hat{\Phi}|V_+ .
\]

Let \( \mathcal{G}_\Phi^* \subset \mathcal{G}_K \) be the pseudogroup defined as in Definition 9.8 by the maps \( \{ \hat{\Phi}_-, \hat{\Phi}_0, \hat{\Phi}_+ \} \subset \mathcal{G}_K \). Also, introduce the symmetric generating set for \( \mathcal{G}_\Phi^* \),

\[
\mathcal{G}_\Phi^{(1)} = \{ \text{Id}, (\hat{\Phi}_-)\pm 1, (\hat{\Phi}_0)\pm 1, (\hat{\Phi}_+)\pm 1 \} .
\]

Then a map \( \varphi \in \mathcal{G}_\Phi^{(n)} \) is a composition of at most \( n \) maps in the collection \( \mathcal{G}_\Phi^{(1)} \), which by definition of these generating maps is just a composition of \( \hat{\Phi} \), or its inverse, restricted to a connected domain of continuity. In particular, for each open set \( U \in \mathcal{D}_\mathcal{M}^n(\hat{\Phi}) \), and \( -n \leq \ell \leq n \), the restriction \( \varphi = \hat{\Phi}^\ell|U \in \mathcal{G}_\Phi^{(n)} \).

Recall that \( d_{R_0} \) denotes the metric on \( R_0 \) defined in [26], and the metric \( d_{K} \) on \( K \) was defined in Section 4 so that \( K \) has unit length, and thus \( \Phi_1 \) is a unit speed flow.

We restrict the action of \( \mathcal{G}_\Phi^* \) to the invariant set \( \mathcal{M}_{R_0} \subset R_0 \). Let \( s(\mathcal{G}_\Phi^*, \mathcal{M}_{R_0}, n, \epsilon) \) be the maximal cardinality of a \( (\mathcal{G}_\Phi^*, n, \epsilon) \)-separated subset of \( \mathcal{M}_{R_0} \). Define the restricted entropy by

\[
h_{GLW}(\mathcal{G}_\Phi^*, \mathcal{M}_{R_0}) = \lim_{\epsilon \to 0} \left\{ \limsup_{n \to \infty} -\ln n \ln(s(\mathcal{G}_\Phi^*, \mathcal{M}_{R_0}, n, \epsilon)) \right\} .
\]

Here is the first result.

**Proposition 20.9.** \( h_{GLW}(\mathcal{G}_\Phi^*, \mathcal{M}_{R_0}) = 0 \) if and only if \( h_{\text{top}}(\Phi_1|\mathcal{M}) = 0 \).

**Proof.** We require some preliminary remarks. As \( R_0 \) is compact submanifold of \( K \), there exists a constant \( A_1 \geq 1 \) so that for \( x, y \in R_0 \) we have

\[
A_1^{-1} d_K(x, y) \leq d_{R_0}(x, y) \leq A_1 d_K(x, y).
\]

The submanifold \( R_0 \) was chosen to be disjoint from the embedded regions \( \mathcal{D}_i \subset \mathcal{W} \) for \( i = 1, 2 \), so there exists some \( \epsilon_2 > 0 \) so that the \( \epsilon_2 \)-closed neighborhood of \( R_0 \) is disjoint from these surfaces. That is, for \( i = 1, 2 \), we have

\[
C_K(R_0, \epsilon_2) = \{ x \in K \mid d_K(x, R_0) \leq \epsilon_2 \} \quad , \quad C_K(R_0, \epsilon_2) \cap \mathcal{D}_i = \emptyset.
\]

Then the flows \( \Phi_1 \) and \( \Psi_1 \) agree on the set \( C_K(R_0, \epsilon_2) \).

Define a function \( \Delta(\epsilon) > 0 \) for \( \epsilon > 0 \) as follows. For \( y \in \mathcal{M}_{R_0} \) let \( s'_y < 0 < s''_y \) be the minimum and maximum values such that \( \{ \Phi_t(y) \mid s'_y \leq t \leq s''_y \} \subset C_K(R_0, \epsilon_2) \). Then for \( x \in \mathcal{M}_{R_0} \) with \( x \neq y \) let \( \Delta(x, y, \epsilon_2) = \min \{ d_K(x, \Phi_t(y)) \mid s'_y \leq t \leq s''_y \} \). Then \( 0 < \Delta(x, y, \epsilon_2) \leq d_K(x, y) \), and we set

\[
\Delta(\epsilon) = \min \{ \Delta(x, y, \epsilon_2) \mid x, y \in \mathcal{M}_{R_0} \text{ and } d_{R_0}(x, y) \geq \epsilon \}.
\]

Observe that \( \Delta(x, y, \epsilon_2) \) is a continuous function of \( x \neq y \), and the set \( \{ (x, y) \mid x, y \in \mathcal{M}_{R_0} \text{ and } d_{R_0}(x, y) \geq \epsilon \} \) is compact, so \( 0 < \Delta(\epsilon) \leq \epsilon \).
Recall that \( \nu_K \) is the constant introduced in Proposition 9.9. As the flow \( \Phi_t \) is smooth, there exists \( A_2 > 1 \) such that for \( x, y \in \mathcal{M} \) and \(-\nu_K \leq t \leq \nu_K\),
\[
A_2^{-1} d_\ell(x, y) \leq d_\ell(\Phi_t(x), \Phi_t(y)) \leq A_2 d_\ell(x, y).
\]

Now, assume that \( h_{GLW}(G\mathcal{M}_{R_0}) = \lambda > 0 \). Then for \( 0 < \epsilon_3 \leq \epsilon_2 \) sufficiently small, and for \( n \) sufficiently large, there is a \((G_{\mathcal{M}}, n, \epsilon_3)\)-separated subset \( \mathcal{E}_n \subset \mathcal{M}_{R_0} \) with cardinality \#\( \mathcal{E}_n \) > \( \exp(n \lambda/2) \). Fix \( n \) large enough so that this estimate holds.

We have by definition 132 and Lemma 20.2 that for each \( 0 \leq \ell \leq n\),
\[
\text{Dom}(\mathcal{F}) \cap \mathcal{M}_{R_0} \subset D^{(\ell)}(\mathcal{F}) \cap \mathcal{M}_{R_0} \subset \bigcup \left\{ U | U \in D^{(\ell)}(\mathcal{F}) \right\}.
\]
Recall that \( C_\Phi(n) \) is the number of connected domains in \( D^{(\ell)}(\mathcal{F}) \), so by the Pigeonhole principle, there exists some connected component \( U \in D^{(\ell)}(\mathcal{F}) \) such that \#\( (\mathcal{E}_n \cap U) \) > \( \exp(n \lambda/2)/C_\Phi(n) \). For \( n \) sufficiently large, we can assume that \( C_\Phi(n) \leq \exp(n \lambda/4) \) by Proposition 20.8. Then for such \( n \), set \( \mathcal{E}_n' = \mathcal{E}_n \cap U \), and we have that \#\( \mathcal{E}_n' \) > \( \exp(n \lambda/4) \). Let \( y \neq x \in \mathcal{E}_n' \), then \( x \) and \( y \) are \((n, \epsilon_3)\)-separated implies there exists \( n \leq \ell_{x,y} \leq n \) such that \( d_{R_0}(\mathcal{F}_\epsilon(x), \mathcal{F}_\epsilon(y)) > \epsilon_3 \).

It may happen that the restricted set \( \mathcal{E}_n' \) satisfies \( \mathcal{E}_n' \cap (U - U) \neq \emptyset \). That is, there exists \( x \in \mathcal{L}_\epsilon \) for some \( n \leq \ell \leq n \). For such \( x \), there exists \( x' \in U \) which is sufficiently close so that the \((n, \epsilon_3)\)-separated condition is again satisfied. Thus, by taking a sufficiently small perturbation of each point in \( \mathcal{E}_n' \), we can assume without loss of generality that \( \mathcal{E}_n' \subset U \). Recall the definition of \( A_1 \) in (137), then for each distinct pair \( x, y \in \mathcal{E}_n' \), there exists \( n \leq \ell_{x,y} \leq n \) such that
\[
d_{R_0}(\mathcal{F}_\epsilon(x), \mathcal{F}_\epsilon(y)) > \epsilon_3/A_1.
\]

By Proposition 9.9, the forward and backward return time to \( R_0 \) for the \( K \)-orbit of any point \( x \in \mathcal{M}_{R_0} \) is bounded by \( \nu_K \). Consequently, for any \( x \in \mathcal{M} \) there exists a least \( 0 \leq t_x < \nu_K \) such that \( \Phi_{t_x}(x) \in \mathcal{M}_{R_0} \).

Set \( T_n = n \nu_K \). For a distinct pair \( x, y \in \mathcal{E}_n' \), let \(-n \leq \ell_{x,y} \leq n \) be as above, and let \( t_x \) be the value such that \( x' = \Phi_{t_x}(x) = \mathcal{F}_\epsilon(x) \), and \( t_y \) such that \( y' = \Phi_{t_y}(y) = \mathcal{F}_\epsilon(y) \). Then \( 0 \leq |t_x|, |t_y| \leq \ell_{x,y} \nu_K < T_n \).

Set \( \epsilon_4 = \epsilon_3/A_1 \), and \( \epsilon_5 = \Delta(\epsilon_4) \leq \epsilon_4 \) for the function \( \Delta(\epsilon) \) defined by (138).

We claim that the set \( \mathcal{E}_n' \subset \mathcal{M} \) is \((\Phi_t, T_n, \epsilon_3)\)-separated. If not, then there exists a distinct pair \( x, y \in \mathcal{E}_n' \) such that \( d_{R_0}(\Phi_t(x), \Phi_t(y)) \leq \epsilon_5 \) for all \(-T_n \leq t \leq T_n \), and this holds for \( t = t_x \) and \( t = t_y \) in particular. It is given that \( d_{R_0}(\mathcal{F}_\epsilon(x), \mathcal{F}_\epsilon(y)) > \epsilon_4 \), so by the definition of \( \epsilon_5 \) and the function \( \Delta(\epsilon) \), we have \( \Delta(x, y, \epsilon_2) \geq \epsilon_4 \).

That is, for all \( t \) with \( s_y' < t < s_y'' \) we have that \( d_{R_0}(\mathcal{F}_\epsilon(x), \mathcal{F}_\epsilon(y)) \leq \epsilon_5 \). If \( s_y' < t_1 - t_2 < s_y'' \), then this implies that \( d_{R_0}(\Phi_{t_1}(x), \Phi_{t_2}(y)) \leq \epsilon_4 \geq \epsilon_5 \) contrary to assumption. If \( s_y' < t_1 - t_2 < s_y'' \) is not satisfied, then \( \Phi_{t_1}(y) \notin C_\Phi(R_0, \epsilon_2) \), so that \( d_{R_0}(\Phi_{t_1}(x), \Phi_{t_2}(y)) \geq \epsilon_2 \geq \epsilon_5 \), and again contrary to assumption.

It follows that \( s(\Phi_t|\mathcal{M}, T_n, \epsilon_5) \geq \exp(n \lambda/4) \).

As \( T_n \) is a linear function of \( n \), this implies that \( h_{top}(\Phi_t|\mathcal{M}) > 0 \), as was to be shown.

The reverse implication of Proposition 20.9 follows by showing that \( h_{GLW}(G\mathcal{M}_{R_0}) = 0 \) implies \( h_{top}(\Phi_t|\mathcal{M}) = 0 \). For this purpose, we use an alternate interpretation of the topological entropy \( h_{top}(\Phi_t|\mathcal{M}) \), in terms of the minimum cardinality of a \((\Phi_t, T, \epsilon)\)-spanning set for \( \mathcal{M} \). The properties of spanning sets used to define the entropy of a map are discussed in greater detail in [10, Chapter 7.2].

For \( T \geq 0 \), introduce the metric \( d_{E}^T \) on \( \mathcal{M} \) where for \( x, y \in \mathcal{M} \),
\[
d_{E}^T(x, y) = \max \{ d_{R_0}(\Phi_t(x), \Phi_t(y)) | -T \leq t \leq T \}.
\]

A subset \( F \subset \mathcal{M} \) is said to be \((\Phi_t|\mathcal{M}, T, \epsilon)\)-spanning if for all \( y \in \mathcal{M} \) there exists \( x \in F \) such that \( d_{E}^T(x, y) \leq \epsilon \). Note that for \( T' > T \) the metric \( d_{E}^T \) is finer than \( d_{E} \), so a \((\Phi_t|\mathcal{M}, T', \epsilon)\)-spanning set \( F \) is also a \((\Phi_t|\mathcal{M}, T, \epsilon)\)-spanning set. Let \( r(\Phi_t|\mathcal{M}, T, \epsilon) \) be the minimal cardinality of a \((\Phi_t|\mathcal{M}, T, \epsilon)\)-spanning set in \( \mathcal{M} \).
Then $r(\Phi_t|\mathcal{M}, T, \epsilon) < \infty$ as $\mathcal{M}$ is compact, and we have the inequalities $r(\Phi_t|\mathcal{M}, T', \epsilon) \geq r(\Phi_t|\mathcal{M}, T, \epsilon)$ for $T' > T$, and $r(\Phi_t|\mathcal{M}, T, \epsilon') \geq r(\Phi_t|\mathcal{M}, T, \epsilon)$ for $0 < \epsilon' < \epsilon$. Then we have

$$
(141) \quad h_{\text{top}}(\Phi_t|\mathcal{M}) = \lim_{\epsilon \to 0} \left\{ \limsup_{T \to \infty} \frac{1}{T} \log(r(\Phi_t|\mathcal{M}, T, \epsilon)) \right\}.
$$

As an application, we have:

**Lemma 20.10.** Suppose that for all $\lambda > 0$, we have that: for $\epsilon > 0$ sufficiently small and all $T > 0$ sufficiently large, there exists a $(\Phi_t|\mathcal{M}, T, \epsilon)$-spanning set $F(T, \epsilon) \subset \mathcal{M}$ with $\# F(T, \epsilon) \leq \exp(T \lambda)$. Then $h_{\text{top}}(\Phi_t|\mathcal{M}) = 0$.

Now, assume that $h_{\text{GLW}}(\mathcal{G}_\Phi^*|\mathcal{M}_{R_0}) = 0$, and let $\lambda > 0$. Then we construct $(\Phi_t|\mathcal{M}, T, \epsilon)$-spanning sets which have growth rate less than $\exp(T \lambda)$. As $\lambda$ can be chosen arbitrarily small, then Lemma 20.10 implies that $h_{\text{top}}(\Phi_t|\mathcal{M}) = 0$, which completes the proof of Proposition 20.9.

Fix $\lambda > 0$ and $0 < \epsilon < \delta_\mathcal{K}$ then set $\epsilon_6 = \epsilon/8$. Then there exists $n_0 > 0$ such that for $n \geq n_0$ we have $s(\mathcal{G}_\Phi^*|\mathcal{M}_{R_0}, n, \epsilon_6) \leq \exp(n \lambda/2)$. Thus, for each $n \geq n_0$ there exists a $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-separated subset $\hat{F}_n \subset \mathcal{M}_{R_0}$ with maximal cardinality which satisfies $\# \hat{F}_n \leq \exp(n \lambda/2)$. Then for each pair $x \neq y \in \hat{F}_n$ there exists $-n \leq \ell_{x,y} \leq n$ such that $x, y \in \text{Dom}(\phi^{\ell_{x,y}})$ and $d_{R_0}(\phi^{\ell_{x,y}}(x), \phi^{\ell_{x,y}}(y)) > \epsilon_6$.

For each $n \geq n_0$, the set $\hat{F}_n$ was chosen to have maximal cardinality. Thus, for each $y \in \mathcal{M}_{R_0}$, there exists $x \in \hat{F}_n$ such that $d_{R_0}(\phi^{\ell}(x), \phi^{\ell}(y)) \leq \epsilon_6$ for all $-n \leq \ell \leq n$. That is, $\hat{F}_n$ is $(\hat{\phi}|\mathcal{M}_{R_0}, n, \epsilon_6)$-spanning.

We consider the restricted set $\hat{\mathcal{F}}_n \cap U$. The set $\hat{\mathcal{F}}_n \subset \mathcal{M}_{R_0}$ is $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-separated for $\mathcal{M}_{R_0}$, hence is $(\hat{\phi}|\mathcal{M}_{R_0}, n, \epsilon_6)$-spanning for $\mathcal{M}_{R_0}$, but this need not imply that $\hat{\mathcal{F}}_n \cap U$ is $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-spanning for $\mathcal{M}_{R_0} \cap U$. If so, then set $\hat{\mathcal{F}}_n^U = \hat{\mathcal{F}}_n \cap U$. Otherwise, if $\hat{\mathcal{F}}_n \cap U$ is not $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-spanning for $\mathcal{M}_{R_0} \cap U$, then we define $\hat{\mathcal{F}}_n^U \subset U$ by adding to the set $\hat{\mathcal{F}}_n \cap U$ sufficiently many points, obtained from $\epsilon_6$-perturbations of points in $\hat{\mathcal{F}}_n - (\hat{\mathcal{F}}_n \cap U)$, so that $\hat{\mathcal{F}}_n^U$ is $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-spanning for $\mathcal{M}_{R_0} \cap U$. This is done as follows. A point $x \in \hat{\mathcal{F}}_n - (\hat{\mathcal{F}}_n \cap U)$ is said to be in the $(\mathcal{G}_\Phi^*, n, \epsilon_6)$-shadow of $U$, if there exists $y \in U$ such that $d_{R_0}(\phi^\ell(x), \phi^\ell(y)) \leq \epsilon_6$ for all $-n \leq \ell \leq n$. Then define $\hat{\mathcal{F}}_n^U$ as follows:

$$
\hat{\mathcal{F}}_n^U = (\hat{\mathcal{F}}_n \cap U) \cup \{ y \in U \mid x \in \hat{\mathcal{F}}_n - (\hat{\mathcal{F}}_n \cap U), \text{ } x \text{ is a shadow point for } U \}.
$$

Set $\epsilon_7 = 2\epsilon_6 = \epsilon/4$, so that the $\epsilon_7$ ball centered at a point $x \in \mathcal{M}_{R_0}$ contains the $\epsilon_6$-ball centered at $\zeta$, for any point $\zeta$ in the $\epsilon_6$-ball centered at $x$. Then by construction, $\hat{\mathcal{F}}_n^U$ is $(\hat{\phi}|\mathcal{M}_{R_0}, n, \epsilon_7)$-spanning for $\mathcal{M}_{R_0} \cap U$. Note that $\# \hat{\mathcal{F}}_n^U \leq \# \hat{\mathcal{F}}_n$.

The next step in the proof is to use the flow $\Phi_t$ of the set $\hat{\mathcal{F}}_n^U$, for $U \in D^{(n)}(\hat{\phi})$, to obtain a $(\Phi_t|\mathcal{M}, T_n, \epsilon)$-spanning set in $\mathcal{M}$, for appropriate $T_n$. There is a technical difficulty that arises in this procedure, due to the fact that the return time for the flow to the space $\mathcal{M}_{R_0}$ is not constant. We require the following observation, that there is a “modulus of continuity” for the time-change along an orbit, with respect to variations of the initial points for flow segments of $\Phi_t$ with bounded lengths.

**Lemma 20.11.** There exists $M_\mathcal{K} > 0$ and $\delta_\mathcal{K} > 0$ so that for all $0 < \epsilon' < \delta_\mathcal{K}$:

Let $x \in \mathcal{M}_{R_0}$ and $|T| \geq 1$ be such that $\xi = \Phi_T(x) \in \mathcal{M}_{R_0}$. Let $n_x$ be such that $\xi = \phi^{n_x}(x)$. For $y, z \in B_{\mathcal{M}_{R_0}}(x, \epsilon') \cap \mathcal{M}_{R_0}$, assume that $d_{R_0}(\phi^{n_x}(x), \phi^{n_x}(y)) > \epsilon'$ for all $0 \leq \ell \leq n_x$, for both $\eta = y$ and $\eta = z$. Let $T'$ be such that $\Phi_{T'}(y) = \phi^{n_x}(y)$, and $T''$ be such that $\Phi_{T'}(z) = \phi^{n_x}(z)$. Then if $d_{R_0}(y, z) < \epsilon'/M_\mathcal{K} |T|$, we have

$$
(142) \quad d_{\mathcal{K}}(\Phi_t(y), \Phi_t(z)) \leq \epsilon' \text{ for all } |t| \leq |T|.
$$

**Proof.** The curves $\{ \Phi_t(\xi) \mid 0 \leq t \leq T \}$ for $\xi \in \{x, y, z\}$ are integral curves for the vector field $\mathcal{K}$. The idea of the proof is that for appropriately chosen $\delta_\mathcal{K}$ the $\mathcal{K}$-orbits segments for $y$ and $z$ are contained in a suitably
small neighborhood of the $\mathcal{K}$-orbit segment for $x$, chosen so that the length of the vector $\mathcal{K}$ along these curves are uniformly close. It then follows that the return times for $y$ and $z$ are also uniformly close. The details of the proof use standard methods of differential equations, and are left to the reader. □

We use Lemma 20.11 to construct a set $\hat{F}_{n}'$ whose points are sufficiently close together, so that the $\Phi_t$ flow of $\hat{F}_{n}'$ yields a $(\Phi_t|\mathcal{M}, T_n', \epsilon)$-spanning set, for a sequence of values $T_n'$ which tend to infinity.

Let $T_n = L_\Phi \cdot n$, and set $\epsilon_8 = \epsilon_7/(2M_\mathcal{K} T_n) = \epsilon_7/(2n L_\Phi M_\mathcal{K})$ for $L_\Phi$ as defined in Lemma 20.4 and $M_\mathcal{K}$ as defined in Lemma 20.11. Note that there exists a constant $A_7 > 0$, which depends only on the geometry of $\mathcal{R}_0$, such that the number of points required for an $\epsilon_8$-spanning set of the disk $D_{\mathcal{R}_0}(x, \epsilon_7) \subset \mathcal{R}_0$, for the metric $d_{\mathcal{R}_0}$, is bounded above by $A_7 (\epsilon_7/\epsilon_8)^2 = A_7 (2n L_\Phi M_\mathcal{K})^2$.

For each $U \in D_\mathcal{M}(\hat{\Phi})$ and each $x \in \hat{F}_{n}'$, choose an $\epsilon_8$-spanning set for $\mathcal{M}_{\mathcal{R}_0} \cap D_{\mathcal{R}_0}(x, \epsilon_7) \cap \overline{U}$,

$$S(U, x, \epsilon_8) = \{x(U, x, i) \mid i \in \mathcal{I}(U, x, \epsilon_8)\} \subset \mathcal{M}_{\mathcal{R}_0} \cap D_{\mathcal{R}_0}(x, \epsilon_7) \cap U,$$

where the index set $\mathcal{I}(U, x, \epsilon_8)$ has cardinality $\# \mathcal{I}(U, x, \epsilon_8) \leq A_7 (2n L_\Phi M_\mathcal{K})^2$. Then set

$$\hat{F}_{n}' = \bigcup_{U \in D_\mathcal{M}(\hat{\Phi})} \bigcup_{x \in \hat{F}_{n}'} S(U, x, \epsilon_8).$$

Observe that $\# \hat{F}_{n}' \leq C_\Phi(n) \cdot \exp(n \lambda/2) \cdot A_7 (2n L_\Phi M_\mathcal{K})^2$.

We next construct a set $F_n$ which is contained in the $\Phi_t$-flow of the set $\hat{F}_{n}'$, for a sequence of sufficiently small increments of the time parameter. Let $M_n$ be the greatest integer with $M_n \leq T_n/\epsilon_7$, and for each $0 \leq t \leq M_n$ set $t_\ell = \ell \cdot \epsilon_7$. Then define

$$F_n = \bigcup_{0 \leq \ell \leq M_n} \Phi_{t_\ell} (\hat{F}_{n}') \subset \mathcal{M}.$$

Observe that $\# F_n = M_n \cdot \# \hat{F}_{n}' \leq L_\Phi \cdot n/\epsilon_7 \cdot C_\Phi(n) \cdot \exp(n \lambda/2) \cdot A_7 (2n L_\Phi M_\mathcal{K})^2$.

Thus, for $n_0 \geq n_0$ sufficiently large, we have that $n \geq n_0$ implies that $\# F_n \leq \exp(n \lambda)$. Set $T_n' = T_n - \nu_\mathcal{K}$.

**Lemma 20.12.** $F_n$ is $(\Phi_t|\mathcal{M}, T_n', \epsilon)$-spanning.

**Proof.** Let $\eta \in \mathcal{M}$, then we must show that there exists $\xi \in F_n$ such that

$$d_{\mathcal{G}}(\Phi_t(\eta), \Phi_t(\xi)) \leq \epsilon \quad \text{for all} \quad -T_n \leq t \leq T_n.$$

First, there exists $0 \leq t_\eta < \nu_\mathcal{K}$ such that $y = \Phi_{-t_\eta}(\eta) \in \mathcal{M}_{\mathcal{R}_0}$. Then there exists $U \in D_{\mathcal{M}}(\hat{\Phi})$ with $y \in \overline{U}$, and $x \in \hat{F}_{n}'$ for which $d_{\mathcal{R}_0}(\Phi^x y), \Phi^y y) \leq \epsilon_7$ for all $-n \leq \ell \leq n$. By the choice of the set $N(U, x)$, there exists $z \in N(U, x)$ for which $d_{\mathcal{R}_0}(y, z) \leq \epsilon_8$. Note that $z \in \hat{F}_{n}'$.

We may assume that $T_n \geq \nu_\mathcal{K} + 1$, as we consider $T_n \to \infty$. Then observe that the hypotheses of Lemma 20.11 are satisfied for $t' = \epsilon_7, T = T_n, x \in \hat{F}_{n}'$ and the pair of points $\{y, z\}$ as above, and so the estimate (142) holds for these points. Thus we have:

$$d_{\mathcal{G}}(\Phi_t(y), \Phi_t(z)) \leq \epsilon_7 = \epsilon/4 \quad \text{for all} \quad |t| \leq T_n.$$

Choose $0 \leq \ell \leq M_n$ so that $|t_\eta - t| \leq \epsilon_7$. Then $d_{\mathcal{G}}(\Phi_{t_\eta}(z), \Phi_{t_\eta}(z)) \leq \epsilon_7$ as the flow $\Phi_t$ has unit speed.

Then for $-T_n \leq t \leq T_n'$, note that $|t + \eta| \leq |T_n - \nu_\mathcal{K}| + |\nu_\mathcal{K}| \leq T_n$, so we have the estimates:

$$d_{\mathcal{G}}(\Phi_t(\eta), \Phi_t(\xi)) = d_{\mathcal{G}}(\Phi_{t_\eta}(\eta), \Phi_{t_\eta}(\xi)) \leq d_{\mathcal{G}}(\Phi_{t_\eta+t_\eta}(\eta), \Phi_{t_\eta+t_\eta}(z)) + d_{\mathcal{G}}(\Phi_{t+t_\eta}(z), \Phi_{t+t_\eta}(z)) \leq \epsilon_7 + \epsilon_7 = \epsilon/2.$$

as was to be shown. □
Finally, to complete the proof of Proposition 20.9, note that $T_n = L_\Phi \cdot n$ is a linear function of $n$, so the growth rate of the sets $F_n$ has an exponential bound $\exp(n \lambda) = \exp(T_n \lambda/L_\Phi)$. As the choice of $\lambda > 0$ was arbitrary, by Lemma 20.10 we conclude that $h_{\text{top}}(\Phi, |\omega|) = 0$. □

There is another entropy invariant associated to $\Phi$, which is defined in terms of the action of the pseudo-group $G^*_K$ on $R_\Phi$ introduced in Definition 9.8, and equipped with the symmetric generating set

$$G^{(1)}_K = \{ \text{Id}, (\psi)^{\pm 1}, (\phi_1^+)^{\pm 1}, (\phi_2^+)^{\pm 1}, (\phi_2^-)^{\pm 1} \}.$$ \hspace{1cm} (146)

Let $h_{\text{GLW}}(G^*_K; R_\Phi)$ denote the pseudogroup entropy associated to the generating set $G^{(1)}_K$ acting on $R_\Phi$.

Recall that the map $\psi \in G^{(1)}_K$ represents the return map for the Wilson flow, and corresponds to the "short-cuts" introduced in Lemma 5.1. This additional generator raises the possibility that the growth rate of $(G^*_K, n, \epsilon)$-separated points may be greater than the growth rate of $(G^*_\Phi, n, \epsilon)$-separated points. On the other hand, the pseudo-group $G^*_\Phi$ is the "full pseudogroup" generated by the return map $\hat{\Phi}$, while the generators for $G^*_K$ form just a subset of these. We use Proposition 9.16 to compare these growth rates, and prove the following:

**PROPOSITION 20.13.** $h_{\text{GLW}}(G^*_K; R_\Phi) > 0$ implies that $h_{\text{GLW}}(G^*_K; R_\Phi) > 0$.

**Proof.** Assume that $h_{\text{GLW}}(G^*_K; R_\Phi) = \lambda > 0$. For $\epsilon > 0$ sufficiently small, and $n$ sufficiently large, let $E_0(n, \epsilon) \subset R_\Phi$ be a $(G^*_K, n, \epsilon)$-separated set with cardinality $\#E_0(n, \epsilon) \geq \exp(n \lambda/2)$. Then for each distinct pair $x, y \in E_0(n, \epsilon)$, there exists $n \leq \ell_{x,y} \leq n$ such that $d_{R_\Phi}(\hat{\Phi}^{\ell_{x,y}}(x), \hat{\Phi}^{\ell_{x,y}}(y)) > \epsilon$.

By Corollary 20.6 for each $x \in R_\Phi$, the orbit $G^*_K(x) \subset R_\Phi$ is syndetic for the constant $\nu_\Phi^*$. Recall that $M_\Phi > 0$ is the greatest integer with $M_\Phi \leq 2\nu_\Phi^*$ then by Corollary 20.7 there exists $0 \leq m_x \leq M_\Phi$ such that $\hat{\Phi}^{-m_x}(x) \in G^*_K(x)$. Also by the proof of Proposition 9.16 there exists $0 \leq \ell_x \leq M_\Phi/2$ such that $\nu(\hat{\Phi}^{\ell_x+y}(x)) < r_\epsilon$. Thus, module changing $\ell_x$ for $\ell_x + 1$, we can further assume that $|z(\hat{\Phi}^{\ell_x+y}(x))| > \delta$ for some $\delta > 0$ independent of the choice of $x$ and $0 \leq \ell_x \leq M_\Phi$.

For each $x \in E_0(n, \epsilon)$ we have associated two indices, $0 \leq \ell_x \leq M_\Phi$ and $0 \leq m_x \leq M_\Phi$. The total number of pairs $\{\ell_x, m_x\}$ is at most $M_\Phi^2$, so there exists values $0 \leq \ell' \leq M_\Phi$ and $0 \leq m' \leq M_\Phi$ such that the set

$$E_0(n, \epsilon)(\ell', m') = \{ x \in E_0(n, \epsilon) \mid \ell_x = \ell' \text{ and } m_x = m' \}$$

has cardinality at least $\#E_0(n, \epsilon)/M_\Phi^2$. Fix such $\ell', m'$ and set $E'_0(n, \epsilon) = E_0(n, \epsilon)(\ell', m')$. Set $E'_0(n, \epsilon) = \hat{\Phi}^{-m'}(E_0(n, \epsilon)) \subset R_\Phi$, which is then $(G^*_K, m' + n, \epsilon)$-separated.

Proposition 9.9 shows that for each $\xi \in R_\Phi$ and $\eta = \hat{\Phi}(\xi)$, the $K$-orbit segment $[\xi, \eta)_K$ has length bounded above by $\nu_K$. Then there is a uniform norm on the derivative $D_\xi \hat{\Phi} : T_\xi K \to T_\eta K$, so there is a uniform upper bound $M_\Phi \geq 1$ on the norm of the derivative matrix of $D_\xi \hat{\Phi}$ and on its inverse $(D_\xi \hat{\Phi})^{-1}$. Thus, for $\xi, \xi' \in R_\Phi \cap \text{Dom}(\hat{\Phi})$, we have

$$\langle M_\Phi \rangle^{\ell'} \cdot d_{R_\Phi}(\xi, \xi') \leq d_{R_\Phi}(\hat{\Phi}^{\ell'}(\xi), \hat{\Phi}^{\ell'}(\xi')) \leq \langle M_\Phi \rangle^{\ell'} \cdot d_{R_\Phi}(\xi, \xi').$$ \hspace{1cm} (147)

For $x \neq y \in E'_0(n, \epsilon)$, set $\xi = \hat{\Phi}^{-m'}(x) \in E'_0(n, \epsilon)$ and $\xi' = \hat{\Phi}^{-m'}(y) \in E'_0(n, \epsilon)$.

Let $\ell_{x,y} = \ell_x + \ell_y + M_\Phi \leq n + 2M_\Phi$, then by the choice of $\ell'$ and $m'$, Corollary 20.6 implies the map $\hat{\Phi}^{\ell_{x,y}} \in G^*_K(1)$. Also, we have the estimate

$$d_{R_\Phi}(\hat{\Phi}^{\ell_{x,y}}(\xi), \hat{\Phi}^{\ell_{x,y}}(\xi')) = d_{R_\Phi}(\hat{\Phi}^{\ell_{x,y}+\ell_{x,y}}(x), \hat{\Phi}^{\ell_{x,y}+\ell_{x,y}}(y)) \geq M_\Phi^{-m'} \cdot d_{R_\Phi}(\hat{\Phi}^{\ell_{x,y}}(x), \hat{\Phi}^{\ell_{x,y}}(y)) > M_\Phi^{-M_\Phi} \cdot \epsilon.$$ \hspace{1cm} (148)

Set $\ell' = M_\Phi^{-M_\Phi} \cdot \epsilon$. Then $E'_0(n, \epsilon)$ is $(2(n + 2M_\Phi) \cdot \nu_K, \ell')$-separated for the action of $G^*_K$ on $R_\Phi$.

These estimates hold for a sequence of integers $n \to \infty$, so it follows that $h_{\text{GLW}}(G^*_K; R_\Phi) \geq \lambda/2 > 0$, as was to be shown. □
The rest of this section is devoted to the study of the entropy invariant \( h_{\text{GLW}}(G_K | \mathcal{M}_{R_0}) \). One approach to the study of the restricted entropy \( h_{\text{top}}(\Phi_t | \mathcal{M}) \) is to calculate the invariant measures for the flow, then estimate the Lyapunov spectrum for the flow on \( \mathcal{M} \) and apply the Margulis-Ruelle Inequality \[30, 43\] to estimate it from above. To show the entropy \( h_{\text{top}}(\Phi_t | \mathcal{M}) = 0 \) it then suffices to show that the Lyapunov spectrum must be trivial for any invariant measure, which is done by analyzing the asymptotic properties of the derivative along the flow. In essence, the idea behind the proof of the following result is analogous, in that we obtain uniform estimates for the expansive properties of the dynamics of the pseudo-group \( G_K \).

**THEOREM 20.14.** \( h_{\text{GLW}}(G_K | \mathcal{M}_{R_0}) = 0 \).

**Proof.** Assume that \( h_{\text{GLW}}(G_K | \mathcal{M}_{R_0}) = \lambda > 0 \). Let \( \epsilon > 0 \) and \( n_\epsilon > 0 \) be such that

\[ s(G_K, \mathcal{M}_{R_0}, n, \epsilon) > \exp(n \lambda/2) \quad \text{for all } n \geq n_\epsilon. \tag{149} \]

Let \( E_n \subset \mathcal{M}_{R_0} \) be a sequence of \( (G_K, n, \epsilon) \)-separated sets such that \( \#E_n \geq \exp(n \lambda/2) \). Actually, it may be necessary to pass to a subsequence \( \{n_i | i = 1, 2, \ldots\} \) to obtain the estimate \[149\], but for simplicity of notation, without loss of generality we assume there exists sets \( E_n \) for all \( n \geq n_\epsilon \) with this property. Then for each pair \( \xi \neq \eta \in E_n \), either \( d_{R_0}(\xi,\eta) > \epsilon \), or else there exists a word \( \varphi \in G_K^{(n)} \) with \( \xi, \eta \in \text{Dom}(\varphi) \), and \( d_{R_0}(\varphi(\xi),\varphi(\eta)) \geq \epsilon \). We show this leads to a contradiction.

Recall that the metric \( d_{R_0} \) on \( R_0 \) is the usual euclidean flat metric, where its sides have lengths 2 \times 4. Choose \( m \) so that

\[ \frac{1}{\sqrt{18}} \cdot \exp(n \lambda/4) < m < \frac{1}{4} \cdot \exp(n \lambda/4), \]

and divide \( R_0 \) into \( 2m \times 4m \) uniform squares with sides of length \( \delta = 1/m \) and diameter \( \sqrt{2}/m^2 \). The number of squares is thus bounded above by \( \frac{1}{2} \cdot \exp(n \lambda/2) \), so by the Pigeonhole principle, for some square region must contain two distinct points of \( E_n \),. Hence, for each \( n \) there exists \( x_n, y_n \in E_n \) with \( d_{R_0}(x_n, y_n) < 1/3 \cdot \exp(-n \lambda/4) \), and \( \varphi_n \in \mathcal{M}(n) \) with \( d_{R_0}(\varphi_n(x_n), \varphi_n(y_n)) > \epsilon \).

For \( \xi \in \text{Dom}(\varphi_n) \), let \( D_\xi(\varphi_n) \) denote the \( 2 \times 2 \) Jacobian matrix of first derivatives of \( \varphi_n \) at the point \( \xi \), and let \( \|D_\xi(\varphi_n)\| \) denote its matrix norm. Then by the Mean Value Theorem, there exist \( w_n \in \text{Dom}(\varphi_n) \) in this same square region containing \( x_n, y_n \) such that \( \|D_{w_n}(\varphi_n)\| \geq \epsilon/3 \cdot \exp(n \lambda/4) \). It follows that the norms \( \|D_{w_n}(\varphi_n)\| \) grow exponentially as a function of \( n \).

We next show that the uniform norms \( \|D_\xi(\varphi)\| \) of the derivative matrices of \( \varphi \in G_K^{(n)} \) admit arbitrarily small exponential bounds as functions of \( n \), which yields a contradiction. We remark that this calculation implies the Lyapunov spectrum of the flow \( \Phi_t \) for any invariant measure supported on \( \mathcal{M} \) is trivial.

For an invertible matrix \( A \), introduce the “symmetric norm” \( \|A\| = \max\{|A|,|A^{-1}|\} \), where \( |A| \) is the usual sup-norm on the linear transformation defined by \( A \).

Let \( D_\xi(\phi_i^+) \) denote the \( 2 \times 2 \) Jacobian matrix of first derivatives of \( \phi_i^+ \) at the point \( \xi \in \text{Dom}(\phi_i^+) \). Define

\[ C(\phi) = \sup \{ ||D_\xi(\phi_i^+)|| | i = 1, 2 & \xi \in \text{Dom}(\phi_i^+) \}. \tag{150} \]

For \( b \geq 1 \), introduce the upper bound

\[ C(\psi, b) = \sup \{ ||D_\xi(\psi^\ell)|| | 0 \leq \ell \leq b \quad \text{and} \quad \xi \in \text{Dom}(\psi^\ell) \}. \tag{151} \]

As the matrix \( D_{\omega_i}(\psi) \) is the identity at the fixed points \( \omega_i \) for \( i = 1, 2 \), for \( \xi \in R_0 \) with \( r(\xi) = 2 \), we have that

\[ \lim_{\ell \to \pm \infty} \frac{\ln ||D_\xi(\psi^\ell)||}{|\ell|} = 0. \]

Thus, for every \( \mu > 1 \), there exists \( n(\psi, \mu) > 0 \) such that

\[ 1 \leq ||D_\xi(\psi^\ell)|| \leq \mu^\ell \quad \text{for} \quad \ell \geq n(\psi, \mu), \xi \in \text{Dom}(\psi^\ell). \tag{152} \]

Recall from Section \[14\] the notion of monotone words \( \mathcal{M}(n) \) of length at most \( n \) in Definition \[14.1\] and that by Proposition \[14.3\] every \( \varphi \in G_K^{(n)} \) admits a factorization \( \varphi = \varphi^+ \circ \varphi^- \), where \( \varphi^+ \in \mathcal{M}(n') \) and ...
\[(\varphi^-)^{-1} \in \mathcal{M}(n') \text{ for integers } n', n'' \text{ with } n' + n'' \leq n. \] For \( \varphi \in \mathcal{M}(n) \) we use this factorization and the estimates \([150], [151], \text{ and } [152]\) to obtain a uniform estimate for the norm \( |||D(\varphi)||| \) as a function of \( n \).

For \( \mu = \exp(\lambda/32) \), choose \( b \geq \max(n(\psi, \mu), (32/\lambda) \cdot \ln(C(\phi))) \), so that \( C(\phi)^{1/b} < \exp(\lambda/32) \). Also, for \( \ell \geq b \geq n(\psi, \mu) \), we have \( 1 \leq |||D(\psi^\ell)||| \leq \exp(\lambda/32) \text{ for all } \xi \in \text{Dom}(\psi^\ell) \).

Given \( \varphi \in \mathcal{M}(n) \) recall the product representation in \([17]\). For the \( \psi \) chosen above, there exists \( i(\varphi, b) \geq 1 \) such that \( \ell_i \geq b \text{ for all } 1 \leq i < i(\varphi, b) \), and \( \ell_i \leq b \text{ for } i = i(\varphi, b) \). Write \( \varphi = \varphi^{(b)} \cdot \varphi^{(b)} \) where \( \varphi^{(b)} \text{ starts with the map } \phi^{(\varphi, b)} \) and \( \varphi^{(b)} \text{ starts with } \psi^0 \). Assume that \( n \geq \max\{n_e, n(\psi, \mu)\} \), where \( n_e \) was introduced in the paragraph after \([149]\).

The factor \( \varphi^{(b)} \text{ contains at most } N_b \text{ generators of the form } \phi^{(\iota)} \), and between each such map is a term \( \psi^{\ell_i} \), so there are at most \( N_b + 1 \text{ such factors with exponents either } \ell_i < b \text{ or } \ell_i > b \). Then
\[
|||D(\varphi^{(b)})||| \leq C(\phi)^{N_b} \cdot C(\psi, b)^{(N_b + 1)} \cdot \exp(\lambda/32). 
\]

The factor \( \varphi^{(b)} \text{ contains at most } n/b \text{ generators of the form } \phi^{(\iota)} \), and between each such generator is a term \( \psi^{\ell_i} \text{ where } \ell_i > b \) by the definition of \( \varphi^{(b)} \). Then
\[
|||D(\varphi^{(b)})||| \leq C(\phi)^{n/b} \cdot \exp(n/\lambda/32) \leq \exp(n/\lambda/32) \cdot \exp(n/\lambda/32) = \exp(n/\lambda/16). 
\]

Combining these estimates, we have:

**Lemma 20.15.** For \( \lambda > 0 \), let \( b \geq \max\{n(\psi, \mu), (32/\lambda) \cdot \ln(C(\phi))\} \). For all \( n \geq \max\{n_e, n(\psi, \mu)\} \), we have
\[
\max\{|||D(\varphi)|||, |||D(\varphi)^{-1}|||\} \leq |||D(\varphi^{(b)})||| \cdot |||D(\varphi^{(b)})||| 
\leq \exp(n/\lambda/32) \cdot \exp(n/\lambda/16) < \exp(n/\lambda/8). 
\]

Now recall that with the assumption that \( h_{GLW}(\mathcal{G}_K\mathcal{M}_R_0) = \lambda > 0 \), then for each \( n \geq n_e \), there exists \( \varphi_n \in \mathcal{M}(n) \text{ and } w_n \in \text{Dom}(\varphi_n) \text{ such that } |||Dw_n(\varphi_n)||| \geq \epsilon \cdot \exp(n/\lambda/4) \). Proposition \([14.3]\) implies that each such word \( \varphi_n \text{ admits a factorization into a monotone decreasing factor and an increasing factor, each of length at most } n \). Apply the estimate \([155]\) to both factors to obtain that for \( n \) sufficiently large,
\[
|||Dw_n(\varphi_n)||| < \exp(n/\lambda/8) \cdot \exp(n/\lambda/8) = \exp(n/\lambda/4). 
\]

For \( n \) sufficiently large this yields a contradiction, which completes the proof of Theorem \([20.14]\). □

### 21. Lamination entropy

The minimal set for a flow is an invariant of topological conjugacy, so represents an “invariant” for the flow. Properties of the minimal set can be used to study and classify the flow as a dynamical system. In the case of a generic Kuperberg flow \( \Phi_t \), the space \( \mathcal{M} \) is the unique minimal set, and is fundamental for the study of the dynamics of the flow as has been seen in previous sections. In this section, we use the zippered lamination structure of \( \mathcal{M} \) to define invariants for the lamination itself, derived from the holonomy pseudogroup for \( \mathcal{M} \). The invariants studied in this section are “entropy-like”. In the next section, we study growth-type invariants for the leaves, and both types of invariants reveal the beautiful subtleties of the class of generic Kuperberg flows.

We first give precise definitions of the maps \([\psi, \overline{\psi}, \overline{\psi}_1, \overline{\psi}_2]\) introduced in Section \([14]\) and of the pseudo-group \( \mathcal{G}_\mathcal{M}^* \) they generate. We then study how this pseudo-group is associated to the holonomy of the zippered lamination, and compare it with the pseudo-group \( \mathcal{G}_\mathcal{K}^* \) introduced in Section \([9]\). These two pseudo-groups are naturally closely related, as the action of \( \mathcal{G}_\mathcal{K}^* \text{ on } \mathcal{R}_0 \) studied in previous sections induces an action on the families of curves in the intersection \( \mathcal{M} \cap \mathcal{R}_0 \) and thus induce maps in \( \mathcal{G}_\mathcal{M}^* \text{ acting on the transverse Cantor set } \mathcal{E} \) which parametrizes these curves.

A key difference is that \( \mathcal{G}_\mathcal{M}^* \) contains maps defined by the holonomy along all paths in the leaves of \( \mathcal{M} \), and not just those paths following a \( \mathcal{K} \)-orbit. In particular, the short-cut maps, which play a role in the study of
the entropy for the \( G_K \) action, arise naturally from the geometry of the leaves of \( \mathcal{M} \). The dynamics of the \( G_{\mathcal{M}}^* \) action on the transverse Cantor set \( \mathcal{C} \) defined in [125] provides an alternate source of invariants for the dynamics of the flow \( \Phi_t \) on \( \mathcal{M} \).

The first invariant studied is the entropy \( h_{GLW}(G_{\mathcal{M}}^*) \) of the action of \( G_{\mathcal{M}}^* \) on the transverse Cantor set \( \mathcal{C} \subset \mathcal{T} \). We relate this entropy to the entropy for the action of the pseudo\( GLW \) \( G_K \) on \( \mathcal{M}_{\mathcal{R}_0} \) as studied in the previous section, and prove that \( h_{GLW}(G_{\mathcal{M}}^*) = 0 \) as is naturally expected.

The main result of this section is that there is a non-zero entropy invariant for the pseudo\( GLW \) \( G_K^* \) which is obtained by considering “lamination slow entropy” \( h_{GLW}(G_{\mathcal{M}}^*) \) for \( 0 < \alpha \leq 1 \). We show in Theorem 21.10 that if the insertion maps \( \sigma_i \) used in the construction of \( K \) have “slow growth”, as defined in Definition 21.11, then \( h_{GLW}^{\alpha/2}(G_{\mathcal{M}}^*) > 0 \) for growth constant \( \alpha = 1/2 \). Thus, even though the flow entropy \( h_{top}(\Phi_t|\mathcal{M}) = 0 \), there is enough “chaos” in the orbits of \( \Phi_t \) and hence in the holonomy action of \( G_{\mathcal{M}}^* \) to imply that it has positive slow entropy. We also note, at the end of the section, how one can obtain \( h_{GLW}(G_{\mathcal{M}}^*) > 0 \) for the usual entropy by modifying properties of the insertions maps \( \sigma_i \), which gives a new insight into the results of the Kuperbergs in [28] Section 8).

Recall that \( \mathcal{T} = \{z = 0\} \cap \mathcal{R}_0 \) is the line segment in \( \mathcal{R}_0 \) transverse to the interiors of most of the leaves of \( \mathcal{M} \), and \( \mathcal{C} \subset \mathcal{T} \) as defined in [125] is a Cantor set by Proposition 10.4. Let \( \mathcal{M}_\mathcal{C} \subset \mathcal{M}_{\mathcal{R}_0} = \mathcal{M} \cap \mathcal{R}_0 \) be the union of the path components of \( \mathcal{M}_{\mathcal{R}_0} \) that contain a point in \( \mathcal{C} \).

The holonomy pseudogroup \( G_{\mathcal{M}}^* \) for the zippered lamination \( \mathcal{M} \) can be defined using a covering of \( \mathcal{M} \) by foliation charts. The proof of Theorem 19.1 introduced the sections \( \mathcal{T}_i \) and their associated Cantor sets \( \mathcal{C}_i \) which form the model spaces for the foliation charts constructed there, and so the holonomy defined using this covering produces a pseudogroup. On the other hand, Corollary 9.14 implies that each leaf in \( \mathcal{M} \) intersects the section \( \mathcal{R}_0 \) so we can alternately define \( G_{\mathcal{M}}^* \) using the induced holonomy maps on the space \( \mathcal{M}_\mathcal{C} \) associated to the transverse Cantor set \( \mathcal{C} \). This reduction yields a pseudogroup \( G_{\mathcal{M}}^* \) which is most closely related to our previous constructions, so we assume that \( G_{\mathcal{M}}^* \) is defined using the space \( \mathcal{C} \). Also, recall that \( \mathcal{M}_0 \) is dense in \( \mathcal{M} \) and the intersection \( \mathcal{M}_0 \cap \mathcal{R}_0 \) is dense in \( \mathcal{M}_{\mathcal{R}_0} \) so the holonomy maps of \( G_{\mathcal{M}}^* \) can be defined by paths in the leaf \( \mathcal{M}_0 \) with endpoints in the transversal \( \mathcal{C} \).

Recall the symmetric generating set for the pseudo\( GLW \) \( G_K^* \)

\[
G_K^* = \{Id, (\psi)^\pm, (\phi_1^\pm)^\pm, (\phi_2^+)^\pm, (\phi_2^-)^\pm\}
\]

which act on the endpoints of the arcs in \( \mathcal{M}_\mathcal{C} \) and so induce actions of the tree \( \mathcal{T}_\psi \) as discussed in Section 14. The vertices of the tree \( \mathcal{T}_\psi \) are points in \( \mathcal{C}_0 \) so we get an induced action on \( \mathcal{C}_0 \). We formalize the definitions of the local homeomorphisms defined on subsets of \( \mathcal{M} \) induced by these maps. We first note that \( \mathcal{M}_\mathcal{C} \) “fibers” over \( \mathcal{C} \) in the following sense:

**Lemma 21.1.** There exists a continuous map \( \pi_{\mathcal{M}} : \mathcal{M}_\mathcal{C} \to \mathcal{C} \), such that for \( \xi \in \mathcal{C} \),

1. \( \pi_{\mathcal{M}}(\xi) = \xi \);
2. \( \pi_{\mathcal{M}}(p^k_i(\xi)) = \xi \) for \( k = 1, 2 \),

where \( p^k_i \) for \( k = 1, 2 \) are the maps introduced in Section 19. The fibers of the map \( \pi_{\mathcal{M}} : \mathcal{M}_\mathcal{C} \to \mathcal{C} \) are compact intervals \( \pi_{\mathcal{M}}^{-1}(\xi) \subset \mathcal{R}_0 \) whose lengths are bounded above.

**Proof.** For each \( \xi \in \mathcal{C} \) there exists a maximal connected closed arc in \( \mathcal{M}_\mathcal{C} \) intersecting \( \mathcal{T} \) at \( \xi \). Let \( p^1_0(\xi) \) be the lower endpoint of this arc contained in \( \{z \leq 0\} \, \), and \( p^0_0(\xi) \) the upper endpoint of this arc contained in \( \{z \geq 0\} \). For \( \eta \in \mathcal{M}_\mathcal{C} \) there is a unique arc with \( \eta \in [p^1_0(\xi), p^0_0(\xi)] \), and we set \( \pi_{\mathcal{M}}(\eta) = \xi \). Then properties (1) and (2) follow by definition.

The continuity of the map \( \pi_{\mathcal{M}} \) follows from the proof of Theorem 19.1. The bound on the lengths of the fibers is a consequence of Theorem 18.4. \( \square \)
For points in the dense subset $\mathcal{C}_0 \subset \mathcal{C}$, the definition of $\pi_{\mathcal{M}}$ is based on the intersections with $T$ of the families of $\gamma_0$ and $\lambda_0$ curves in $R_0$. That is, each $\xi \in \mathcal{C}_0$ has the form
\begin{equation}
\xi = \gamma_0(t_1, \ell_1; \ldots; t_n, \ell_n) \cap T \quad \text{or} \quad \xi = \lambda_0(t_1, \ell_1; \ldots; t_n, \ell_n) \cap T.
\end{equation}
Each such curve is defined by the labeling of its endpoints denoted by $p_0^1(\xi)$ for the lower endpoint and $p_0^2(\xi)$ for the upper endpoint. Then for $\eta \in \mathcal{M}_0 \cap R_0$ in a $\gamma_0$ or $\lambda_0$ curve which is an arc, the application $\pi_{\mathcal{M}}$ takes the point $\eta$ to the intersection with $T$ of the $\gamma_0$ or $\lambda_0$ curve which contains it.

The map $\phi_k^+$ for $k = 1, 2$ induces maps $\bar{\phi}_k$ with domains defined by
\begin{equation}
\text{Dom}(\bar{\phi}_k) = \{ \xi \in \mathcal{C} \mid p_0^k(\xi) \in \text{Dom}(\phi_k^+) \}.
\end{equation}
The maps are then formally defined by:
\begin{align*}
\bar{\phi}_1(\xi) &= \pi_{\mathcal{M}}(\phi_1^+(p_0^1(\xi))) \quad \text{for} \quad \xi \in \text{Dom}(\bar{\phi}_1) \\
\bar{\phi}_2(\xi) &= \pi_{\mathcal{M}}(\phi_2^+(p_0^2(\xi))) \quad \text{for} \quad \xi \in \text{Dom}(\bar{\phi}_2).
\end{align*}
The map $\bar{\phi}_k$ has inverse $\bar{\phi}_k^{-1}$ defined on the image of $\bar{\phi}_k$. The action of the maps $\phi_k^+$ on the $\gamma_0$ curves in $\mathcal{M}_0$ are illustrated in Figure 34 and the action of the induced maps $\bar{\phi}_k$ on the vertices of the tree $T_\psi$ are illustrated in Figure 37 as discussed in Section 14. Note that each map $\bar{\phi}_k$ increases the level of the curve in $\mathcal{M}_0$ defining a point $\xi \in \mathcal{C}$ by 1, for $k = 1, 2$.

Next, we define the map $\bar{\psi} \in \mathcal{G}_{\mathcal{M}}$ induced by the map $\psi$. Recall from the discussion in Section 9 that the Wilson flow reverses direction at the annulus $\mathcal{A} = \{ z = 0 \} \subset \mathcal{W}$, and is anti-symmetric with respect to $\mathcal{A}$. Define the domain of $\bar{\psi}$ by
\begin{equation}
\text{Dom}(\bar{\psi}) = \{ \xi \in \mathcal{C} \mid z(p_0^1(\xi)) < 0 \& \ z(\psi_-(p_0^2(\xi))) \leq 0 \},
\end{equation}
for $\psi_-$ as defined in (152). The map $\bar{\psi}$ is then formally defined by:
\begin{equation}
\bar{\psi}(\xi) = \pi_{\mathcal{M}}(\psi_-(p_0^2(\xi))) \quad \text{for} \quad \xi \in \text{Dom}(\bar{\psi}).
\end{equation}
The map $\bar{\psi}$ has inverse $\bar{\psi}^{-1}$ defined on the image of $\bar{\psi}$. The action of $\psi$ and its inverse on the $\gamma_0$ curves in $\mathcal{M}_0$, is illustrated in Figure 34 as the vertical maps. The action of the induced map $\bar{\psi}$ on the vertices of the tree $T_\psi$ is given by translation along the center lines in $T'_\psi$, as discussed in Section 14. Note that the map $\bar{\psi}$ preserves the level.

**Definition 21.2.** Let $\mathcal{G}_{\mathcal{M}}$ be the pseudogroup generated by the collection of maps
\begin{equation}
\mathcal{G}_{\mathcal{M}}^{(1)} = \{ T_\psi, \bar{\psi}, \bar{\psi}^{-1}, \bar{\phi}_1, \bar{\phi}_2, \bar{\phi}_2^{-1} \}.
\end{equation}
Let $\mathcal{G}^*_{\mathcal{M}}$ be the pseudo-group formed by the compositions of maps in $\mathcal{G}_{\mathcal{M}}^{(1)}$ and the restrictions of these compositions to open subsets of their domains in $\mathcal{C}$.

**Remark 21.3.** We do not need to consider the maps $\phi_i^-$, since for $\xi \in \mathcal{C}$ such that $p_0^i(\xi) \in \text{Dom}(\phi_i^-)$ we have that $p_0^i(\xi) \in \text{Dom}(\phi_i^+ \circ \psi^-)$ and
\begin{equation}
\pi_{\mathcal{M}}((\phi_i^-)^{-1}(\xi)) = \pi_{\mathcal{M}}(\phi_i^+ \circ \psi^-(p_0^i(\xi))).
\end{equation}

The action of $\mathcal{G}_{\mathcal{M}}$ on $\mathcal{C}$ has a geometric model. Identify the points of $\mathcal{C}_0$ with the vertices of $T_\psi$. Then the discussion in Section 14 gives the actions of the generators in (159) on the tree $T_\psi$. This remark is the basis for the proof of the following:

**Proposition 21.4.** The holonomy pseudogroup $\mathcal{G}_{\mathcal{M}}$ of $\mathcal{M}$ is the pseudogroup acting on $\mathcal{C}$ defined by the holonomy maps associated to leafwise paths in $\mathcal{M}$.

**Proof.** The leaf $\mathcal{M}_0$ is dense in $\mathcal{M}$, so it suffices to consider the holonomy associated to a path $\sigma: [0, 1] \to \mathcal{M}_0$ with $\sigma(0), \sigma(1) \in \mathcal{C}_0$. As each $\xi \in \mathcal{C}_0$ corresponds to a vertex of $T_\psi$, we can assume that the path $\sigma: [0, 1] \to T_\psi$. Recall from Section 14 that $T'_\psi \subset T'_\lambda = A \cap \mathcal{M}_0$ consists of the line segments in $\mathcal{M} \cap A$ which are formed by the intersection of $A$ with the simple propellers in the construction of $\mathcal{M}_0$. Then $T_\psi$ is formed by adding
continuous curve segments in $\mathfrak{M}_0$ joining the line segments in $T_\Phi'$, as is illustrated in Figure 36. Thus, the edges of the tree $T_\Phi$ consists of two types, those which belong to $T_\Phi'$ and the added connecting paths.

If the path $\sigma$ traverses a connecting segment, then the holonomy map this induces corresponds to the action of one of the maps $\{\overline{\sigma}_1, \overline{\sigma}_2, \overline{\sigma}_2^{-1}\}$. If the path $\sigma$ traverses a segment in $T_\Phi'$, then the holonomy map this induces corresponds to the action of one of the maps $\{\overline{\psi}, \overline{\psi}^{-1}\}$. Thus, the holonomy maps defined by such $\sigma$ are contained in $G_{\mathfrak{M}}$.

Conversely, given a word in $G_{\mathfrak{M}}$ we can associate a path $\sigma: [0, 1] \to T_\Phi$ with $\sigma(0), \sigma(1) \in \mathfrak{C}_0$ using the same correspondence of the generators in $G_{\mathfrak{M}}^{(1)}$ with segments in $T_\Phi$, so that every word in $G_{\mathfrak{M}}$ is associated with the holonomy along a leafwise path.

As noted in Section 14, $T_\Phi$ is a tree except for the loop based at the basepoint vertex $\omega_0$. Thus, a path $\sigma: [0, 1] \to T_\Phi$ is homotopic with endpoints fixed, to a path which is monotone in level. We derive from this remark the existence of normal forms for words in $G_{\mathfrak{M}}$ exactly as in Proposition 14.3.

The word length on $G_{\mathfrak{M}}$ is defined as before, where $\|\bar{\varphi}\| \leq n$ if $\bar{\varphi}$ can be expressed as a composition of at most $n$ maps in $G_{\mathfrak{M}}^{(1)}$. Also, define monotone words in $G_{\mathfrak{M}}$ in analogy with Definition 14.1.

DEFINITION 21.5. A word $\bar{\varphi} \in G_{\mathfrak{M}}^*$ is said to be monotone increasing if it is written in the form

$$\bar{\varphi} = \psi^m \circ \overline{\sigma}_{j_m} \circ \psi^{m-1} \circ \ldots \circ \overline{\sigma}_{j_2} \circ \psi^1 \circ \overline{\sigma}_{j_1}$$

where each $j_k = 1, 2$ and $\ell_k \geq 0$. Set $M_{\mathfrak{M}}(0) = \{T\bar{d}\}$, and define

$$M_{\mathfrak{M}}(n) = \{\bar{\varphi} \in G_{\mathfrak{M}}^* | \bar{\varphi} \text{ monotone } \& \|\bar{\varphi}\| \leq n\} ; \quad M_{\mathfrak{M}}(\infty) = \bigcup_{n \geq 0} M_{\mathfrak{M}}(n).$$

The proof of the upper bound estimate on the function $\#M_{\mathfrak{M}}(n)$ in Proposition 14.5 applies verbatim to the function $\#M_{\mathfrak{M}}(n)$, and we have:

PROPOSITION 21.6. For each $b \geq 1$, there is a polynomial function $P_b(n)$ of $n$ such that the cardinality of the set $M_{\mathfrak{M}}(n)$ satisfies

$$\#M_{\mathfrak{M}}(n) \leq P_b(n) \cdot 2^{(n/b)}.$$  

The following result is analogous to Corollary 14.6 and the proof follows in the same way.

COROLLARY 21.7. The cardinality of the set $M_{\mathfrak{M}}(n)$ of monotone words of length at most $n$ in $G_{\mathfrak{M}}$ satisfies

$$\lim_{n \to \infty} \frac{\ln(\#M_{\mathfrak{M}}(n))}{n} = 0.$$ 

We then have the following result, which is analogous to Proposition 14.3 and follows from Proposition 21.4 and the comments afterwards.

PROPOSITION 21.8. Let $\bar{\varphi} \in G_{\mathfrak{M}}^*$ with $\|\bar{\varphi}\| \leq n$. Then there exists a factorization $\bar{\varphi} = \bar{\varphi}^+ \circ \bar{\varphi}^-$, where $\bar{\varphi}^+ \in M_{\mathfrak{M}}(n')$ and $(\bar{\varphi}^-)^{-1} \in M_{\mathfrak{M}}(n'')$ for integers $n', n''$ with $n' + n'' \leq n$. Moreover, we have $\text{Dom}(\bar{\varphi}) \subset \text{Dom}(\bar{\varphi}^+ \circ \bar{\varphi}^-)$.

The factorization $\bar{\varphi} = \bar{\varphi}^+ \circ \bar{\varphi}^-$ is said to be the normal form for the word $\bar{\varphi}$.

We conclude this discussion of the structure of $G_{\mathfrak{M}}$ with some remarks concerning the relation between the actions of $G_{\mathfrak{M}}$ and $G_K$. First, recall that the domain $D(\overline{\Psi})^-$ of the the induced action of the Wilson map $\psi_-$ contains the segment $J_0 \subset \mathfrak{R}_0$ as defined in (64). and $\psi_-$ defines a strict contraction of $J_0$ to the fixed point $\omega_1$ which is the upper endpoint of $J_0$. For the $\gamma_0$ and $\lambda_0$ curves in $\mathfrak{R}_0$ with lower endpoint in $J_0$, the action of $\psi_-$ on these curves induces the map $\psi$ which is a strict contraction to $\omega_0 \in \mathfrak{C}$. Thus, the holonomy pseudogroup
\( \mathcal{G}_{2\mathbb{R}} \) contains a contracting fixed point, which is just the holonomy along the loop in \( T_\phi \) containing the point \( \phi_0 \).

The second remark concerns the action of \( \psi \) on the endpoints of curves in \( \mathfrak{M}_\mathbb{C} \) and the action of \( \overline{\psi} \) on \( T_\phi \). Let \( \xi \in \mathfrak{C} \) be defined by a \( \gamma_0 \) or \( \lambda_0 \) curve in \( \mathfrak{M}_\mathbb{C} \) with endpoints \( x = p_0^1(\xi) \) and \( \overline{x} = p_0^0(\xi) \) where \( r(x) = r(\overline{x}) = r_0 > 2 \). Let \( k_x \geq 0 \) be the exponent such that \( \overline{x} = \psi^{k_x}(x) \). Then \( x_\ell = \psi^\ell(x) \) for \( 0 \leq \ell \leq k_x \) is a sequence of points with \( r(x_\ell) = r_0 \) and \( z(x_{\ell+1}) > z(x_\ell) \) for \( 0 \leq \ell < k_x \). Let \( m_x \) be the greatest integer with \( m_x \leq k_x/2 \). By the anti-symmetry of the Wilson flow, we have \( z(x_{m_x}) < 0 \) and \( z(x_{m_x+1}) \geq 0 \). That is, the action of \( \psi \) on the curves with lower endpoints \( \{ x_\ell \mid 0 \leq \ell \leq m_x \} \) produces a sequence of curves whose intersections with \( T \) have decreasing radius. For \( k_x \) even, the closest curve to \( I_0 \) in the sequence, the innermost curve, corresponds to the endpoint \( x_{m_x} \). When \( k_x \) is odd, the closest curve degenerates to the single point \( x_{m_x+1} \) with \( z(x_{m_x+1}) = 0 \). The action of \( \psi \) on the endpoints \( \{ x_\ell \mid m_x < \ell < k_x \} \) then reverses this process, where the endpoints \( x_0 \) and \( x_{k_x} \) correspond to the same curve in \( \mathfrak{M}_\mathbb{C} \) and thus the same point in \( \mathfrak{C} \).

For the induced map \( \overline{\psi} \in \mathcal{G}_{2\mathbb{R}}^* \) acting on \( T_\phi \), its action on the vertex \( \xi \in \mathfrak{C}_0 \) corresponding to the \( \gamma_0 \) or \( \lambda_0 \) curve chosen, defines a sequence of vertices \( \overline{\psi}(\xi) = \pi_\mathbb{R}(x_\ell) \) in \( T_\phi \) tending to the tip of the propeller containing \( \xi \), as in Figure 36. However, if \( k_x \) is even, the point \( \xi_{m_x} \) is then the furthest point along the sequence, which is closest to the tip of the propeller. If \( k_x \) is odd, \( \xi_{m_x+1} \) is the furthest point along the sequence. In terms of the normal forms for words in \( \mathcal{G}_K^* \) defined in Proposition 14.3 and the normal forms for words in \( \mathcal{G}_{2\mathbb{R}}^* \) defined in Proposition 21.8, this implies that a power \( \psi^\ell \) appearing in (71) can collapse to a power \( \overline{\psi}^m \) appearing in (160) with \( m < \ell \). We will say that the action of \( \mathcal{G}_{2\mathbb{R}}^* \) has “leaf short-cuts”, which correspond to the holonomy of a path which goes from a point on one side of a propeller, to a point on the opposite side, avoiding the trip that the action of \( \mathcal{G}_K^* \) must follow to the extremal end of the propeller, to get to the point on the opposite side.

Finally, note that Hypothesis 12.2 and the structure of the propellers imply that for \( \xi \in Dom(\overline{\psi}) \) we have \( r(\overline{\psi}(\xi)) < r(\xi) \), as \( r(\psi^\ell(p_0^0(\xi)) = r(p_0^1(\xi)) \).

We next discuss the entropy associated to the action of the pseudo-group \( \mathcal{G}_{2\mathbb{R}}^* \) on \( \mathfrak{C} \). Let \( \mathcal{T} = A \cap \mathbb{R}_0 \) have the metric defined by the radial coordinate \( r \), and endow \( \mathfrak{C} \subset \mathcal{T} \) with the restricted metric, denoted by \( d_\mathfrak{C} \). For \( \epsilon > 0 \), say that \( \xi_1, \xi_2 \in \mathfrak{C} \) are \((n,\epsilon)\)-separated if there exists \( \overline{\xi} \in \mathcal{G}_{2\mathbb{R}}^*(n) \) such that \( \xi_1, \xi_2 \) are in the domain of \( \overline{\xi} \), and \( d_\mathfrak{C}(\overline{\xi}(\xi_1), \overline{\xi}(\xi_2)) > \epsilon \). A finite set \( S \subset \mathfrak{C} \) is said to be \((n,\epsilon)\)-separated if each distinct pair \( \xi_1, \xi_2 \in S \) is \((n,\epsilon)\)-separated. Let \( s(\mathcal{G}_{2\mathbb{R}}^*, n, \epsilon) \) be the maximal cardinality of an \((n,\epsilon)\)-separated subset of \( \mathfrak{C} \).

Then as in (129), define the entropy of \( \mathcal{G}_{2\mathbb{R}}^* \) by:

\[
(164) \quad h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) = \lim_{\epsilon \to 0} \left\{ \limsup_{n \to \infty} \frac{1}{n} \ln(s(\mathcal{G}_{2\mathbb{R}}^*, n, \epsilon)) \right\}.
\]

The entropy \( h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) \) is closely related to the entropy \( h_{\text{GLW}}(\mathcal{G}_K^*|\mathfrak{M}_\mathbb{C}) \), as the action of \( \mathcal{G}_K^* \) on \( \mathbb{R}_0 \) and \( \mathcal{G}_{2\mathbb{R}}^* \) on \( \mathfrak{C} \) are “almost intertwined” by the projection map \( \pi_\mathbb{R}: \mathfrak{M}_\mathbb{C} \to \mathfrak{C} \) defined in Lemma 21.1. The relation between the entropy for a group action under a factor map suggests that \( h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) \) should be bounded above by \( h_{\text{GLW}}(\mathcal{G}_K^*|\mathfrak{M}_\mathbb{C}) \), which vanishes by Theorem 20.14.

The standard argument for factor maps used to prove this result does not actually suffice in the situation we consider, as the “leaf short-cuts” in \( \mathcal{G}_{2\mathbb{R}}^* \) (discussed above) imply there are actions in \( \mathcal{G}_K^* \) which are collapsed by the map \( \pi_\mathbb{R} \). We will use instead a more straightforward approach to the estimation of \( h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) \) based on the fact that the space \( \mathfrak{C} \) is contained in an interval, and the function \#\( \mathcal{G}_{2\mathbb{R}}^*(n) \) has subexponential growth. The proof of the following result is reminiscent of the methods used in [20].

**Theorem 21.9.** Let \( K \) be a generic Kuperberg plug, then \( h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) = 0 \).

**Proof.** Suppose that \( h_{\text{GLW}}(\mathcal{G}_{2\mathbb{R}}^*) = \lambda > 0 \), then there exists \( \epsilon > 0 \) and a subsequence of sets \( \hat{E}_n \subset \mathfrak{C} \) which are \( \epsilon \)-separated by elements of \( \mathcal{G}_{2\mathbb{R}}^*(n) \) and \#\( \hat{E}_n \) is \( \exp(n, \lambda/2) \). We show this yields a contradiction. Fix a choice of \( n = n_i \) such that the set \( \hat{E}_n \) satisfies \#\( \hat{E}_n \) is \( \exp(n, \lambda/2) \) and is \( \epsilon \)-separated by elements of \( \mathcal{G}_{2\mathbb{R}}^*(n) \).
Then for each pair \( \xi \neq \xi' \in \tilde{E}_n \) there exists \( \varphi \in \mathcal{G}_{3R}^{(n)} \) such that \( d_E(\varphi(\xi), \varphi(\xi')) > \epsilon \). We may assume that the word \( \varphi \) has the normal form \( \varphi = \varphi^+ \circ \varphi^- \) where each of \( \varphi^+ \) and \( (\varphi^-)^{-1} \) is a monotone word as in \eqref{160}.

Proposition \ref{21.6} and Corollary \ref{21.7} imply that the function \( \#\mathcal{G}_{3R}^{(n)} \) has subexponential growth. It follows that for \( n \) sufficiently large, there exists \( \varphi \in \mathcal{G}_{3R}^{(n)} \) and a subset \( \tilde{E}_\varphi \subset \tilde{E}_n \cap \text{Dom}(\varphi) \) with \( \#\tilde{E}_\varphi > \exp(n \lambda/4) \)
and for each \( \xi \neq \xi' \in \tilde{E}_\varphi \) we have \( d_E(\varphi(\xi), \varphi(\xi')) > \epsilon \).

Thus we conclude that the set \( \varphi(\tilde{E}_\varphi) \subset \mathcal{E} \subset T \) is \( \epsilon \)-separated. This is clearly impossible for \( n \) sufficiently large, as the length of \( T \) is finite.

The above proof that \( h_{GLW}(\mathcal{G}_{3R}^*) = 0 \) depends fundamentally on the estimate of the growth rate of the reduced word function \( \#\mathcal{G}_{3R}^{(n)} \). This estimation follows from Proposition \ref{21.6}, which implies that this function has exponential growth of arbitrarily small exponent, hence must have subexponential growth. This suggests considering a more sensitive entropy-type invariant, which detects growth rates that are subexponential, yet faster than any polynomial function, in order to obtain non-vanishing dynamical invariants of the action of \( \mathcal{G}_{3R}^* \) on \( \mathcal{E} \). It turns out that such invariants exist in the literature.

The slow entropy of a map was introduced in the works of Katok and Thouvenot \cite{25} and Cheng and Li \cite{8}, and we adapt this idea for the action of \( \mathcal{G}_{3R}^* \). For \( 0 < \alpha < 1 \), define the \( \alpha \)-entropy of \( \mathcal{G}_{3R}^* \), or just the slow entropy, by

\begin{equation}
(165) \quad h_{GLW}^\alpha(\mathcal{G}_{3R}^*) = \lim_{\epsilon \to 0} \left\{ \limsup_{n \to \infty} \frac{1}{n^\alpha} \ln(s(\mathcal{G}_{3R}^*, n, \epsilon)) \right\}
\end{equation}

where \( 0 \leq h_{GLW}^{\alpha}(\mathcal{G}_{3R}^*) \leq \infty \). If \( h_{GLW}^{\alpha}(\mathcal{G}_{3R}^*) > 0 \) and \( 0 < \beta < \alpha \), then \( h_{GLW}^{\beta}(\mathcal{G}_{3R}^*) = \infty \).

Note that for \( 0 < \alpha < 1 \), the function \( \exp(n^\alpha) \) grows faster than any polynomial function, but is slower than any exponential function, so the invariant \( h_{GLW}^{\alpha}(\mathcal{G}_{3R}^*) \) has the right character for measuring the complexity of the dynamics of \( \mathcal{G}_{3R}^* \).

The entropy dimension for a continuous transformation \( T: X \to X \) of a compact metric space \( X \) was introduced by de Carvalho \cite{10}, and studied further by Cheng and Li \cite{8}. We define an analogous invariant for the pseudo-group action of \( \mathcal{G}_{3R}^* \) on \( \mathcal{E} \), given by the number \( 0 \leq D(\mathcal{G}_{3R}^*) \leq 1 \) defined by

\begin{equation}
(166) \quad D(\mathcal{G}_{3R}^*) = \inf \{ \alpha \mid 0 < \alpha \leq 1 \text{ and } h_{GLW}^{\alpha}(\mathcal{G}_{3R}^*) = 0 \}.
\end{equation}

The proof of Theorem \ref{21.9} suggests that to show \( h_{GLW}^{\alpha}(\mathcal{G}_{3R}^*) \neq 0 \) for some \( \alpha \), it suffices to estimate the growth rate of the function \( \#\mathcal{G}_{3R}^{(n)} \) more precisely. This, in turn, requires a more precise accounting for what monotone words of the form \( \varphi \) actually exist in \( \mathcal{G}_{3R}^{(n)} \). This is an extremely difficult question to answer in general, but we next describe further hypotheses on the construction of \( K \), the notion of “slow growth” in Definition \ref{21.11} and “fast growth” in Definition \ref{21.12} below, which makes a lower bound estimate possible. We obtain three results, Theorems \ref{21.10} \ref{21.17} and \ref{21.18} below. Due to the highly technical nature of the proofs and the estimates required, we present in detail only the proof of the following:

**THEOREM 21.10.** Let \( \Phi_t \) be a generic Kuperberg flow. If the insertion maps \( \sigma_j \) have “slow growth” in the sense of Definition \ref{21.11}, then \( h_{GLW}^{1/2}(\mathcal{G}_{3R}^*) > 0 \), and thus \( 1/2 \leq D(\mathcal{G}_{3R}^*) \leq 1 \).

The strategy of the proof of Theorem \ref{21.10} is to develop an “admissibility criterion” for strings \( I = (\ell_1, \ldots, \ell_m) \) and \( J = (j_1, \ldots, j_m) \) such that for each admissible pair \( (I, J) \), we obtain a point \( \xi_{(I,J)} \in \mathcal{E}_0 \) by the expression

\begin{equation}
(167) \quad \xi_{(I,J)} = \varphi_{(I,J)}(\omega_0) = \psi_m^j \circ \varphi_j \circ \psi_j^{m-1} \circ \cdots \circ \varphi_{j_2} \circ \psi_j^{2} \circ \varphi_j \circ \psi_j(\omega_0).
\end{equation}

Then observe that the images of the maps \( \varphi_j \) on their domains in \( \mathcal{M}_\mathcal{E} \) are contained in the disjoint compact regions bounded by the parabolic curves \( \Gamma_0(a) \) and \( \Lambda_0(a) \), according to whether \( j = 1 \) or \( 2 \). The parabolic curves \( \Gamma_0(a) \) and \( \Lambda_0(a) \) define disjoint compact subsets \( I(\Gamma_0), I(\Lambda_0) \subset \mathcal{E} \), where \( I(\Gamma_0) \) consists of the points
\(\xi \in \mathcal{C}\) whose corresponding path component in \(\mathfrak{M}_{R_0}\) is contained in the closure of the region bounded by \(\Gamma_0\), and similarly for \(I(\Lambda_0)\). Then choose \(\varepsilon_0 > 0\) such that

\[
\varepsilon_0 < \inf \{ d_{\mathcal{C}}(\pi_{\mathcal{M}}(\xi), \pi_{\mathcal{M}}(\xi')) \mid \xi \in I(\Gamma_0), \xi' \in I(\Lambda_0) \}.
\]

Two points \(\xi = \overline{\varphi(I,J)}(\omega_0), \xi' = \overline{\varphi(I,J)}'(\omega_0) \in \mathcal{C}\) where \(J\) and \(J'\) have \(\ell_m = \ell'_m = 0\), and terminate with distinct indices \(j_m \neq j'_m\) will then be \(\varepsilon_0\)-separated in \(\mathcal{C}\). The strategy is then to construct collections of points via formula (167) which are \((\mathcal{G}_{\mathfrak{M}}, \varepsilon_0, n)\)-separated. The key technical problem is to estimate the number of admissible strings which give rise to \((\mathcal{G}_{\mathfrak{M}}, \varepsilon_0, n)\)-separated points in this way, using words in \(\mathcal{G}_{K}^*\).

Recall that the difference between \(\mathcal{G}_{\mathfrak{M}}^*\) and \(\mathcal{G}_{K}^*\) is that in the former we allow the leaf short-cuts which replace terms \(\psi^\ell\) in (71) with terms \(\overline{\psi}^\ell\) in (160) where \(m \leq \ell\). The leaf short-cuts only arise when applying the map \(\psi\) repeatedly to a point \(\xi \in R_0\) with \(z(\xi) < 0\), such that we eventually have \(z(\psi^\ell(\xi)) > 0\). In particular, they do not arise for the orbits \(p_0(j; 1, \ell) = \psi^\ell(\phi_2^+(\omega_j))\) for \(j = 1, 2\).

Introduce the involution \(\iota: R_0 \to R_0\) defined by \(\iota(r, \pi, z) = (r, \pi, -z)\). For a point \(\xi \in \mathcal{C}\), the action of \(\iota\) switches the endpoints \(p_0^+(\xi)\) and \(p_0^-(\xi)\) of the \(\gamma_0\) or \(\lambda_0\) arc in \(R_0\) through \(\xi\), as in the proof of Lemma 21.1. In particular, \(\iota\) induces the identity map on \(\mathcal{C}\).

Extend the symmetric generating set in (146) for the pseudo\-group \(\mathcal{G}_{K}^*\) by adding the element \(\iota\) restricted to \(\mathfrak{M}_{R_0}\), to obtain

\[
\mathcal{G}_{K}^{(1)} = \{Id, \iota, (\psi)^\pm 1, (\phi_1^+)^\pm 1, (\phi_2^-)^\pm 1, (\phi_2^+)^\pm 1\}.
\]

Let \(\mathcal{G}_{K}^*\) denote the augmented pseudo\-group generated by this set. Then the problem is to obtain criteria for the existence for sufficient numbers of words in \(\mathcal{G}_{K}^*\) that generate \((\mathcal{G}_{\mathfrak{M}}^*, \varepsilon_0, n)\)-separated sets in \(\mathcal{C}\) with sufficient growth rates.

The proof that the composition \(\overline{\varphi(I,J)}\) in (167) is defined at \(\omega_0\) requires technical estimates analogous to those used in the proof of Theorem 17.1. The existence of a point \(\xi(I,J)\) is interpreted as a statement about the composition of generators of the pseudo\-group \(\mathcal{G}_{K}^*\), which requires a careful analysis of the dynamics of \(\mathcal{G}_{K}^*\) near the special points \(\omega_i \in R_0\). This leads to estimates which give sufficient conditions for \((I, J)\) to be admissible, so that the point \(\xi(I,J)\) is well-defined.

For simplicity we assume that \(a = 0\), for \(a\) as in Remark 13.3.

Observe that for a word \(\overline{\varphi(I,J)}\) as in (167), the initial composition \(\overline{\varphi^d(I)} \circ \overline{\varphi_{J_i}}(\omega_0)\) corresponds to a \(\gamma_0\) or \(\lambda_0\) curve whose lower endpoint is the point \(p_0(j_1; 1, \ell_1) \in J_0\). Then \(\pi_{\mathfrak{M}}(\phi_{j_2}^+(p_0(j_1; 1, \ell_1)))\) must lie in the domain of the remaining factor \(\overline{\varphi(I,J')}\) defined by \(\overline{\varphi(I,J')} = \overline{\varphi(I,J)} \circ \overline{\phi_{j_2}^-} \circ \overline{\psi^\ell} \circ \overline{\phi_{j_2}^+}\). However, if \(j_2 = 2\), it is necessary to apply the involution \(\iota\) to the point \(p_0(j_1; 1, \ell_1)\) to obtain a point in the domain of \(\phi_2^+\), as will be seen in the subsequent construction of separated sets.

Recall the integer valued function \(N(r)\) for \(2 < r < 3\) introduced in Section 6, which is defined using the function \(\delta(r)\) in (19). The function \(N(r)\) is an upper bound on the number of insertion maps that can be applied to a point \(\xi \in R_0\) with \(r(\xi) = r\), and \(N(r)\) is unbounded as \(r\) decreases to \(r = 2\). In particular, \(N(r)\) for \(r = r(\phi_{j_2}^+(p_0(j_1; 1, \ell_1)))\) provides an upper bound on the number of subsequent maps \(\overline{\varphi_{j_2}^-}\) which can appear in the remaining term \(\overline{\varphi(I,J')}\) for an admissible word \(\overline{\varphi(I,J)}\). Thus, a more precise estimate on the growth rate of the function \(N(r)\) for \(r > 2\) will yield estimates on the growth rates of sets of \((\epsilon, n)\)-separated points for \(\mathcal{G}_{\mathfrak{M}}^*\).

The growth rate of the function \(N(r)\) for \(r > 2\) is closely related to the geometry of the embedding maps \(\phi_i^+\) for \(i = 1, 2\) near the special points \(\omega_i \in R_0\) as defined in (27), which we next consider. We use the assumptions in Hypotheses 12.2 and 17.2 to analyze the properties of the maps \(\phi_i^+\) on sufficiently small neighborhoods of the points \(\omega_i\).

Recall that the first transition point for the forward \(K\)-orbit of \(\omega_i\) is the special entry point \(p_i^- \in E_i\) and its backward \(K\)-orbit is the special exit point \(p_i^+ \in S_i\) as illustrated in Figure 16. For \(\epsilon > 0\), define the closed
squares in $\mathbf{R}_0$ centered on the special points $\omega_i$ for $i = 1, 2$, 
\[ S_{\mathbf{R}_0}(\omega_i, \epsilon) = \{(r, \pi, z) \mid |r - 2| \leq \epsilon \text{ and } |z - (-1)^i| \leq \epsilon \}, \]
and let $D_{\mathbf{R}_0}(\omega_i, \epsilon) \subset \mathbf{R}_0$ be the closed ball centered at $\omega_i$ with radius $\epsilon$. Then $S_{\mathbf{R}_0}(\omega_i, \epsilon/\sqrt{2}) \subset D_{\mathbf{R}_0}(\omega_i, \epsilon)$.

We next choose $\epsilon_0' > 0$ so that the various generic hypotheses apply to the points in $S_{\mathbf{R}_0}(\omega_i, \epsilon_0')$. Recall that the constant $\epsilon_0 > 0$ was chosen in Hypothesis 12.2 so that the estimate (94) holds for the Wilson vector field $\mathcal{K}$ on the disk $D_{\mathbf{R}_0}(\omega_1, \epsilon_0)$. Recall that for the same $\epsilon_0$, we assumed that Hypothesis 17.2 on the insertion maps $\sigma_i$ for $i = 1, 2$, holds for $2 \leq r_0 \leq 2 + \epsilon_0$ and $\theta_i - \epsilon_0 \leq \theta \leq \theta_i + \epsilon_0$.

Choose $0 < \epsilon_0' \leq \epsilon_0/\sqrt{2}$ sufficiently small so that $S_{\mathbf{R}_0}(\omega_i, \epsilon_0') \subset \text{Dom} (\phi_i^+)$ for $i = 1, 2$.

Moreover, require that the forward $\Phi_i$-flow of $S_{\mathbf{R}_0}(\omega_i, \epsilon_0')$ to the surface $E_i$ is contained in the rectangular domain for Hypothesis 17.2. This automatically holds for the $r$ coordinate, as the flow $\Phi_i$ preserves the radius coordinate along these trajectories, but the condition $\theta_i - \epsilon_0 \leq \theta \leq \theta_i + \epsilon_0$ on the image in $E_i$ imposes a restraint on the choice $\epsilon_0'$.

Thus, Hypothesis 12.2 applies for the Wilson return map $\psi$ near $\omega_i$ and Hypothesis 17.2 applies for the radial coordinates of the return map $\phi_i^+$ near $\omega_i$.

Consider first the map $\phi_i^+$. By Hypothesis 12.1 the “parabolic function” $z \mapsto r(\phi_i^+(2, \pi, z))$ has a minimum value 2 at $z = -1$. Then
\begin{equation}
(170) \quad 2 = r(\phi_i^+(\omega_1)) < r(\phi_i^+(r, \pi, z)) \quad \text{for all } (r, \pi, z) \neq \omega_1 \text{ with } r \geq 2.
\end{equation}

Moreover, Hypothesis 17.2 implies that the images of the vertical lines $r = c$ for $2 \leq c \leq 2 + \epsilon_0'$ in the neighborhood of $\omega_1$ are mapped by $\phi_i^+$ to parabolic curves, so that $z \mapsto r(\phi_i^+(c, \pi, z))$ has a minimum value at a unique value $z = \zeta_i(c)$. Thus the forward orbit of $(c, \phi, \zeta_i(c))$ intersects $E_1$ in a point with $z$-coordinate equal to $-1$. Set $\rho_1(c) = r(\phi_i^+(c, \pi, \zeta_i(c))) > 2$.

For each $2 \leq c \leq 2 + \epsilon_0'$ the function $z \mapsto r(\phi_i^+(c, \pi, z))$ has vertex point $(\zeta_i(c), \rho_1(c))$. The graph of this function near the point $(\zeta_i(c), \rho_1(c))$ has upward parabolic shape, where $\zeta_i(c)$ gives the “offset” of the parabolic vertex along the $z$-axis.

Hypothesis 17.2 implies that the function $c \mapsto \zeta_i(c)$ is a smooth function of $c$ with $\zeta_i(2) = -1$ and $-1 - \epsilon_0' \leq \zeta_i(c) \leq -1 + \epsilon_0'$. We also have that the function $c \mapsto \rho_1(c)$ is smooth, with $\rho_1(2) = 2$ and $c \mapsto \rho_1(c)$ is strictly increasing for $c > 2$. Moreover, there exists $0 < \alpha_1 \leq \beta_1$ such that for $2 \leq c \leq 2 + \epsilon_0'$ we have the quadratic bounds
\begin{equation}
(171) \quad \rho_1(c) + \alpha_1 \cdot (z - \zeta_i(c))^2 \leq r(\phi_i^+(c, \pi, z)) \leq \rho_1(c) + \beta_1 \cdot (z - \zeta_i(c))^2.
\end{equation}

The map $\phi_i^+$ near $\omega_2$ admits a similar analysis, yielding functions $c \mapsto \zeta_2(c)$ and $c \mapsto \rho_2(c)$ with the properties $1 - \epsilon_0' \leq \zeta_2(c) \leq 1 + \epsilon_0'$ for $2 \leq c \leq 2 + \epsilon_0'$ and constants $0 < \alpha_2 \leq \beta_2$ for which there is the quadratic estimate
\begin{equation}
(172) \quad \rho_2(c) + \alpha_2 \cdot (z - \zeta_2(c))^2 \leq r(\phi_i^+(c, \pi, z)) \leq \rho_2(c) + \beta_2 \cdot (z - \zeta_2(c))^2.
\end{equation}

Set $\alpha_\Phi = \min\{\alpha_1, \alpha_2\}$ and $\beta_\Phi = \max\{\beta_1, \beta_2\}$.

We also have that the function $c \mapsto \zeta_i(c)$ is smooth with $\zeta_i(2) = (-1)^i$, for $i = 1, 2$, so there exists a constant $\hat{\zeta} \geq 0$ so that
\begin{equation}
(173) \quad |\zeta_i(c) - (-1)^i| \leq \hat{\zeta} \cdot |c - 2| \quad \text{for } 2 \leq c \leq 2 + \epsilon_0' .
\end{equation}

That is, the vertical offset of each parabolic curve $z \mapsto r(\phi_i^+(c, \pi, z))$ has a linear bound as a function of $(c-2)$, for $2 \leq c \leq 2 + \epsilon_0'$.

Recall that we require an estimate on the function $N(r)$ introduced in Section 6, for $r$ near 2, and this is defined in terms of the function $\delta(r)$ defined in (19). Using the normal forms (171) and (172), observe that $\delta(r) = \min\{\rho_1(r), \rho_2(r)\}$ for $2 \leq r \leq 2 + \epsilon_0'$. We introduce two classes for the functions $\rho_i$ which are
determinant in the behavior of the function $N(r)$. Note that each function $\rho_i$ is smooth and strictly increasing, so its derivative $\rho'_i(r) \geq 1$ for all $2 \leq r \leq 2 + \epsilon'_0$.

**DEFINITION 21.11.** The insertions $\sigma_j$ are said to have slow growth if the derivatives $\rho'_i(2) = 1$ for $i = 1, 2$. In this case, there exists $C_\rho > 0$ and uniform estimates on $\rho_i(r)$,

$$r < \rho_i(r) \leq r + C_\rho (r - 2)^2 \quad \text{for} \ 2 < r \leq 2 + \epsilon'_0.$$  \hfill (174)

**DEFINITION 21.12.** The insertions $\sigma_i$ are said to have fast growth if there exists $\lambda > 1$ such that derivatives $\rho'_i(r) \geq \lambda$ for $2 \leq r \leq 2 + \epsilon'_0$ with $i = 1, 2$. In this case, we have the uniform estimate,

$$\rho_i(r) \geq 2 + \lambda (r - 2) \quad \text{for} \ 2 \leq r \leq 2 + \epsilon'_0.$$  \hfill (175)

These two properties of the insertion maps are sufficient to obtain the required estimates on the domains for the maps $\Psi_{r,h}$ as discussed above. We also require some preliminary estimates which describe the quantitative behavior of the map $\psi$ near the special point $\omega_1$. The derivation of these estimates is similar to those in Section 17 so the arguments are only briefly sketched.

Let $\xi = (r, \pi, z) \in \mathbb{R}_o$. Define times $0 = T_0(\xi) < T_1(\xi) < T_2(\xi) < \cdots$ where $\psi^\ell(\xi) = \Psi_{T_\ell(\xi)}(\xi)$ for $\ell \geq 0$ such that $\psi^\ell(\xi)$ is defined. Then $r(\psi^\ell(\xi)) = r(\xi)$, and by (175) we have

$$z(\psi^\ell+1(\xi)) - z(\psi^\ell(\xi)) = \int_{T_{\ell}(\xi)}^{T_{\ell+1}(\xi)} g(\Psi_s(\xi)) \, ds.$$  \hfill (176)

The return time for the flow $\Psi_t$ at $\xi$ is $2\pi \cdot r(\xi)$, so for $\xi$ with $2 \leq r(\xi) \leq 2 + \epsilon_0$, the domain of the integral in (176) satisfies $4\pi \leq T_{\ell+1}(\xi) - T_\ell(\xi) \leq (4 + 2\epsilon'_0)\pi$. Moreover, Hypothesis 12.2 implies that $g(r, \theta, z)$ is a non-decreasing function of $r \geq 2$, hence (176) yields

$$z(\psi^\ell(r', \pi, z)) \geq z(\psi^\ell(r, \pi, z)) \quad \text{for} \ r' > r \geq 2.$$  \hfill (177)

Recall that $g(\xi) = 1$ if $r(\xi) \geq 2 + \epsilon_0$, so for $\xi \in \mathbb{R}_o$ with $r(\xi) \geq 2 + \epsilon_0$, the orbit $\Psi_t(\xi)$ escapes the plug $\mathbb{W}$ at a time $t = 4 - z(\xi) \leq 6$, hence does not complete a full revolution. Moreover, if $\xi \in \mathbb{R}_o$ satisfies $r(\xi) = 2$ and $-2 \leq z \leq -1 - \epsilon_0$, then $\psi(\xi)$ is defined and satisfies $-(1 + \epsilon_0) < z(\psi(\xi)) < -1$.

In particular, let $\xi_0 = \phi^+_j(\omega_j)$ for $j = 1, 2$, so that $r(\xi_0) = 2$, then we have

$$z(p_0(j; 1, 0)) = z(\psi(\xi_0)) > -(1 + \epsilon_0).$$

We can thus take $\ell_0 = 1$ in Lemma 17.5 so that for $\ell \geq 1$, the estimates (96) and (97) hold for $\psi^\ell(\xi_0) = p_0(j; 1, \ell)$.

**LEMMA 21.13.** There exists constants $0 < \mu_1 = 4\pi \lambda_1 \leq 4\pi \lambda_2 < \mu_2$ and $b_0 > 0$ such that for $\ell \geq b_0$, for $j = 1, 2$, the point $p_0(j; 1, \ell)$ satisfies

$$-1 - 1/(\mu_1 \ell) < z(p_0(j; 1, \ell)) < -1 - 1/(\mu_2 \ell).$$  \hfill (178)

**Proof.** Following the notation as in Lemma 17.5 set $\mu_1 = 4\pi \lambda_1$ and choose $4\pi \lambda_2 < \mu_2 < 8\pi \lambda_2$. Then for $b_0 \geq C_3/(\mu_2 - 4\pi \lambda_2)$, (178) follows from (96) of Lemma 17.5. \hfill \Box

Consider next the case where $\xi \in \mathbb{R}_o$ with $-2 \leq z(\xi) < -1$ and $2 < r(\xi) < 2 + \epsilon'_0$. Then the $W$-orbit $\Psi_t(\xi)$ escapes from $\mathbb{W}$ in finite time, and thus $\psi^\ell(\xi)$ is only defined for a finite range of $\ell$, where $\ell \to \infty$ as $r(\xi)$ approaches 2. The next two results give an estimate for the range of $\ell$ for which $z(\psi^\ell(\xi)) \leq -1 + \epsilon'_0$, using methods analogous to those used in the proofs of Lemmas 17.8, 17.9 and 17.11.

**LEMMA 21.14.** There exists constants $U_g > 0$ and $0 < \epsilon_1 < \epsilon'_0$ such that for all $0 < \epsilon \leq \epsilon_1$ and $\xi \in \mathbb{R}_o$ with $z(\xi) \leq -(1 + \epsilon)$ and $2 \leq r(\xi) \leq 2 + \epsilon$, then there exists $\ell_\xi > 0$ so that

$$-1 - \epsilon \leq z(\psi^\ell(\xi)) \leq -1 + \epsilon \quad \text{for all} \quad \ell_\xi \leq \ell \leq \ell_\xi + U_g/\epsilon.$$  \hfill (179)
Proof. Recall from Section [12] that Hypothesis [12.2] and condition [44] imply there exists constants $A_g, B_g, C_g$ such that the quadratic form $Q_g(u, v) = A_g u^2 + 2B_g uv + C_g v^2$ defined by the Hessian of $g$ at $\omega_1$ is positive definite. The remainder term for the quadratic Taylor approximation to $g(r, \theta, z)$ is dominated by a scalar multiple of $d\psi(\xi, O_1)^3$, where $d\psi(\xi, O_1) = \sqrt{(r - 2)^2 + (z + 1)^2}$ denotes the distance from $\xi = (r, \theta, z)$ to the periodic orbit $O_1$. As $Q_g(u, v)$ is positive definite, there exists $0 < \epsilon_2 \leq \epsilon'_0$ so that for $\xi = (r, \theta, z)$
\begin{equation}
|g(\xi) - Q_g(r - 2, z + 1)| \leq Q_g(r - 2, z + 1)/4 \quad \text{for } d\psi(\xi, O_1) \leq \epsilon_2.
\end{equation}

Let $\lambda_2$ denote the maximum eigenvalue of the quadratic form $Q_g$. Then for $0 < \epsilon \leq \epsilon_2/\sqrt{2}$ we have by
\begin{equation}
\max \{g(\xi) \mid \xi = (r, \theta, z), \ |z + 1| \leq \epsilon \text{ and } |r - 2| \leq \epsilon\} \leq 4\lambda_2 \epsilon^2.
\end{equation}

Let $\epsilon_1 = \min\{\epsilon_2/\sqrt{2}, 1/(24\pi \lambda_2)\}$.

Given $0 < \epsilon \leq \epsilon_1$ and $\xi \in \mathbb{R}_0$ with $z(\xi) \leq -(1 + \epsilon)$ and $2 \leq r(\xi) \leq 2 + \epsilon$, we show (179) holds.

First, note there exist $t_1 \geq 0$ so that $z(\Psi_{t_1}(\xi)) = -(1 + \epsilon)$. Let $t_2 \geq t_1$ be the first subsequent time for which $\Psi_{t_2}(\xi) \in \mathbb{R}_0$. Then there exists $\ell_\xi \geq 0$ so that $\Psi_{t_2}(\xi) = \psi^{\ell_\xi}(\xi)$. Set $\xi_\ast = \Psi_{t_2}(\xi)$.

Note that $z(\xi_\ast) \geq -(1 + \epsilon)$ and $t_2 - t_1 \leq 2\pi r(\xi) < 6\pi$, so by (176) and (181) we have
\begin{equation}
0 \leq z(\Psi_{t_2}(\xi)) - z(\Psi_{t_1}(\xi)) < 4\lambda_2 \epsilon^2 \cdot 6\pi = 24\pi \lambda_2 \epsilon^2.
\end{equation}

As $z(\Psi_{t_1}(\xi)) = -(1 + \epsilon)$ this yields
\begin{equation}
-(1 + \epsilon) \leq z(\xi_\ast) < -(1 + \epsilon) + 24\pi \lambda_2 \epsilon^2 \leq -(1 + \epsilon) + \epsilon = -1.
\end{equation}

The same reasoning yields, for $\ell > 0$ such that $z(\psi^\ell(\xi_\ast)) \leq -1 + \epsilon$, then
\begin{equation}
z(\psi^\ell(\xi_\ast)) - z(\psi^{\ell-1}(\xi_\ast)) < 24\pi \lambda_2 \epsilon^2 \leq \epsilon.
\end{equation}

Set $U_g = 1/(24\pi \lambda_2)$. It then follows by applying (183) recursively, that for $\ell \leq U_g/\epsilon$ we have
\begin{equation}
0 < z(\psi^\ell(\xi_\ast)) - z(\xi_\ast) \leq \ell \cdot 24\pi \lambda_2 \epsilon^2 \leq (U_g/\epsilon) \cdot (24\pi \lambda_2 \epsilon^2) = \epsilon.
\end{equation}

It follows that for $0 \leq \ell \leq U_g/\epsilon$ we have
\begin{equation}
-(1 + \epsilon) \leq z(\xi_\ast) < z(\psi^\ell(\xi_\ast)) \leq z(\xi_\ast) + \epsilon \leq -1 + \epsilon
\end{equation}

which was to be shown.

Next, we give a form of density estimate for the flow $\Phi_t$. Recall that for $j = 1, 2$, the function $\zeta_j(\epsilon)$ is the “offset” of the vertex of the parabolic graph $z \mapsto \phi_j^+(c, \pi, z)$. The function satisfies $\zeta_j(2) = (-1)^j$ and there is $\zeta_\ast > 0$ so that the bounds (173) hold for $j = 1, 2$.

**Lemma 21.15.** Let $0 < \epsilon_1 < \epsilon'_0$ be the constant of Lemma [21.14]. Then there exists $L_g > 0$ so that for all $0 < \epsilon \leq \epsilon_1$ and $\xi \in \mathbb{R}_0$ with $-(1 + \epsilon) \leq z(\xi) \leq -(1 + \epsilon/2)$ and $2 \leq r(\xi) \leq 2 + \min\{1, 1/\zeta_\ast\} \cdot \epsilon/2$, then there exists $0 \leq \ell_\ast \leq L_g/\epsilon$ so that
\begin{equation}
0 < |z(\psi^{\ell_\ast}(\xi)) - (-1)^j \zeta_j(r(\xi))| < \epsilon.
\end{equation}

**Proof.** If $\zeta_1(r(\xi)) \leq -1$ or $\zeta_2(r(\xi)) \geq 1$, then there is nothing to show. In fact, we need only consider the case where $r_0 = r(\xi)$ is such that $2 < r_0 \leq \epsilon/2 \cdot \min\{1, 1/\zeta_\ast\}$ and $-1 - \epsilon \leq \zeta_1(r_0) < -1 + \zeta_\ast \cdot (r_0 - 2) \leq -1 + \epsilon/2$. It then suffices to estimate the least value of $\ell_\ast > 0$ such that $\psi^{\ell_\ast}(\xi) > -1 - \epsilon/2$.

Let $\lambda_1$ denote the minimum eigenvalue of the quadratic form $Q_g$. By (180) there is a lower bound
\begin{equation}
\min \{g(\xi) \mid \xi = (r, \theta, z), \ |z + 1| \leq \epsilon \text{ and } |r - 2| \leq \epsilon\} \geq \lambda_1 \epsilon^2/(4 \cdot 1.01) \geq \lambda_1 \epsilon^2/5.
\end{equation}

By (176) and (186), and using that the flow $\Phi_t$ has return time at least $4\pi$ for $r_0 > 2$, if $-1 - \epsilon \leq z(\xi) < z(\psi^{\ell_\ast}(\xi)) \leq -1 - \epsilon/2$, then we have
\begin{equation}
0 \leq z(\psi(\xi)) - z(\xi) \geq 4\pi \lambda_1 \epsilon^2/5.
\end{equation}
Thus, the least \( \ell_* \) satisfies the estimate 
\[
\ell_* \cdot 4\pi \lambda_1 \varepsilon^2/5 \leq \varepsilon/2,
\]
so for \( L_g = 5/(8\pi \lambda_1) \) there exists \( \ell_* \leq L_g/\varepsilon \) such that
\[\text{[155]}\]
holds.

After these preliminary considerations, we return to the proof of Theorem \[21.10\]. We consider monotone words in \( G_{2n}^* \) of the form \[160\], and their lifts to monotone words in \( \hat{G}_K^* \).

We assume that the insertion maps \( \sigma_j \) satisfy Definition \[21.11\] with \( C_\rho \) the constant so that \[174\] is satisfied. Also, recall \( \beta_\Phi = \max\{\beta_1, \beta_2\} \) for the constants \( \beta_j \) as defined by \[171\], \[172\], and \( \zeta \geq 0 \) was defined so that the estimate \[173\] holds. Then define \( C_\Phi = \max\{1, C_\rho, \beta_\Phi\} \).

Let \( 0 < \varepsilon < \min\{\epsilon_1, 1/C_\Phi\} \) for \( \epsilon_1 \) as defined in Lemma \[21.14\].

By Lemma \[21.13\] there exists an integer \( b_1 \geq 1 \) such that for \( \ell \geq b_1 \), for \( k = 1, 2 \), the point \( p_0(k; 1, \ell) \) satisfies the estimates in \[178\]. For \( m \geq 1 \), let \( b_m = m b_1 \). Then \( 1/(\mu_1 b_m) \leq \varepsilon/m \leq 1/(m C_\Phi) \).

Now consider strings \( I = (\ell_1, \ldots, \ell_m) \) and \( J = (j_1, \ldots, j_m) \). We develop a criteria for when the point \( \xi(I, J) = \varphi(I, J)(\omega_0) \) as in \[167\] is defined. Take \( p_0(j_1; 1, 0) = \phi^*_j(\omega_j) \) for \( j_1 \geq 2 \). Assume that \( \ell_1 \geq b_m \) and set \( (r_1, \pi, z_1) = \psi^{(1)}(p_0(j_1; 1, 0)) = p_0(j_1; 1, \ell_1) \). Then \( r_1 = 2 \) and \( z_1 < -1 \). Set \( v_1 = |z_1 + 1| \) so that 
\[
0 < v_1 \leq \varepsilon/m \text{ by the choice of } \ell_1.
\]

For \( j_2 = 1 \), we have \( \phi^*_1(p_0(j_1; 1, \ell_1)) = p_0(j_1; 1, \ell_1; 1, 0) \), while for \( j_2 = 2 \), we use the involution \( \iota \) to obtain 
\[
\phi^*_2(\iota(p_0(j_1; 1, \ell_1))) = \phi^*_2(p_0(j_1; 2, \ell_1)) = p_0(j_1; 2, \ell_1; 1, 0).
\]

These points are well-defined by the choice of \( \ell_1 \).

Set \( r_2 = r(p_0(j_1; j_2, \ell_1; 1, 0)) \), then by the quadratic estimates \[171\] or \[172\] for \( r_1 = 2 \) and so \( \rho_{j_1}(r_1) = 2 \), we have
\[
2 + \alpha_\Phi \cdot v_1^2 \leq r_2 \leq 2 + \beta_\Phi \cdot v_1^2 \leq 2 + \beta_\Phi \cdot (\varepsilon/m)^2 < 2 + \varepsilon/m^2
\]
since \( \beta_\Phi \varepsilon \leq C_\Phi \varepsilon < 1 \). Thus, \( r_2 < 2 + \varepsilon/m \).

Now set \( b'_m = b_m + mL_g/\varepsilon \) for \( L_g = 5/(8\pi \lambda_1) \) as defined in Lemma \[21.15\], so \( b'_m \leq m \{1/\mu_1 + 5/(8\pi \lambda_1)\}/\varepsilon \). Then by Lemmas \[21.14\] and \[21.15\] applied for \( \varepsilon/m \) we can choose \( \ell_2 \leq b'_m \) so that
\[
(r_2, \pi, z_2) = p_0(j_1; j_2, \ell_1; 1, \ell_2) = \psi^{(2)}(p_0(j_1; j_2, \ell_1; 1, 0))
\]
is defined with \( |z_2 + 1| \leq \varepsilon/m \), and the vertical “offset” along the line \( r = r_2 \) is given by
\[
v_2 = |z_2 - \zeta_jz_2(r_2)| \leq \varepsilon/m.
\]

For \( j_3 = 1, 2 \), we get
\[
p_0(j_1; j_2, \ell_1; 1, \ell_2; 1, 0) = \phi^*_3(p_0(j_1; j_2, \ell_1; 1, \ell_2)) \]
\[
p_0(j_1; j_2, \ell_1; 2, \ell_2; 1, 0) = \phi^*_3(\iota(p_0(j_1; j_2, \ell_1; 1, \ell_2)))
\]

Let \( r_3 = r(p_0(j_1; j_2, \ell_1; j_3, j_3; 2, 1, 0)) \), then by the quadratic estimates \[171\] or \[172\], the “slow” estimate \[174\], and the inductive estimates \[188\] and \[189\], we have
\[
r_3 \leq \rho_{j_3}(r_2) + \beta_\Phi \cdot v_2^2
\]
\[
\leq [r_2 + C_\rho \cdot (r_2 - 2)^2] + [\beta_\Phi \cdot (\varepsilon/m)^2]
\]
\[
\leq [2 + \beta_\Phi \cdot (\varepsilon/m)^2 + [C_\rho \cdot (\beta_\Phi \cdot (\varepsilon/m)^2)^2] + [\beta_\Phi \cdot (\varepsilon/m)^2]
\]
\[
= 2 + 2\beta_\Phi \cdot \varepsilon^2/m^2 + C_\rho \cdot \beta_\Phi \cdot \varepsilon^4/m^4
\]
\[
\leq 2 + 2\varepsilon/m^2 + C_\rho \cdot \varepsilon^2/m^4 < 2 + 3\varepsilon/m^2
\]
where the last inequality follows from \( C_\rho \cdot \varepsilon^2/m^4 \leq C_\Phi \cdot \varepsilon^2/m^4 < \varepsilon/m^4 \leq \varepsilon/m^2 \).

Then by Lemma \[21.14\] applied for \( \varepsilon/m \), we can choose \( \ell_3 \leq b'_m \) so that
\[
(r_3, \pi, z_3) = p_0(j_1; j_2, \ell_1; j_3, j_3, j_3; 2, 1, 0) = \psi^{(3)}(p_0(j_1; j_2, \ell_1; j_3, j_3, j_3, j_3; 2, 1, 0))
\]
is defined with \( |z_3 + 1| \leq \epsilon/m \), and the vertical “offset” along the line \( r = r_3 \) is given by
\[
v_3 = |z_3 - \zeta_{j_3}(r_3)| \leq \epsilon/m .
\]

We continue recursively, assuming the definitions as above for \( 1 \leq i \leq k \), and that the following inductive assumptions hold for \( 1 < i \leq k \):
\[
\ell_i \leq b'_m , \quad |z_i + 1| < \epsilon/m , \quad 2 \leq r_i \leq 2 + (1 + 2i) \epsilon/m^2 , \quad v_i \leq \epsilon/m
\]
Also assume that \( r_k \leq \min\{1/\sqrt{C}, 1\} \cdot \epsilon/2 \). Then for \( j_{k+1} = 1, 2 \), we get
\[
p_0(j_1; j_2, \ell_1; j_3, \ell_2; \cdots ; 1, \ell_k; 1, 0) = \phi_{k+1}^+(p_0(j_1; j_2, \ell_1; j_3, \ell_2; \cdots ; 1, \ell_k))
\]
and set \( r_{k+1} = r(p_0(j_1; j_2, \ell_1; j_3, \ell_2; \cdots ; j_{k+1}, \ell_k; 1, 0)) \).

We require one additional assumption and a small calculation to complete the inductive step of the construction. Suppose that \((1+2k) = m\), then \( C_\rho \epsilon < 1 \) by choice of \( \epsilon \), so \((1+2k) < m/\sqrt{C_\rho} \). Thus \((1+2k)^2 < m^2/\epsilon C_\rho \) and so \((1+2k)\epsilon/m^2 < 1/C_\rho \) which yields \( C_\rho((1+2k)\epsilon/m^2)^2 < \epsilon/m^2 \).

Finally, use the quadratic estimates \([171]\) or \([172]\), the “slow estimate” \([174]\), the inductive estimates \([188]\) and \([189]\), and the small calculation above to obtain
\[
r_{k+1} \leq \rho_{k+1}(r_k) + \beta_\cdot v_k^2 \leq [r_k + C_\rho(r_k - 2)^2] + [\beta_\cdot (\epsilon/m^2)^2] \leq 2 + (1 + 2k) \epsilon/m^2 + \epsilon/m^2 + C_\rho((1 + 2k)\epsilon/m^2)^2 \leq 2(1 + 2(k + 1)) \epsilon/m^2
\]
Then by Lemma \([21.14]\) applied for \( \epsilon/m \), we can choose \( \ell_{k+1} \leq b_m \) so that
\[
(r_{k+1}, \pi, z_{k+1}) = p_0(j_1; j_2, \ell_1; j_3, \ell_2; \cdots ; j_{k+1}, \ell_k; 1, 0) = \psi_{k+1}^+(p_0(j_1; j_2, \ell_1; j_3, \ell_2; \cdots ; j_{k+1}, \ell_k; 1, 0))
\]
is defined with \( |z_{k+1} + 1| \leq \epsilon/m \), and the vertical “offset” along the line \( r = r_{k+1} \) is given by
\[
v_{k+1} = |z_{k+1} - \zeta_{j_{k+1}}(r_{k+1})| \leq \epsilon/m .
\]
which completes the recursive step.

We use the constructions above to obtain lower bound estimates on the number \( s(G_{2n}, n, \epsilon) \) of \((n, \epsilon)\)-separated words for the action of \( G_{2n}^* \) on \( \mathcal{C} \).

For \( 0 < \epsilon < \min\{\epsilon_1, 1/\sqrt{C_F} \} \) as before and \( \delta = \min\{1, 1/\sqrt{C} \} \cdot \epsilon/2 \), we construct orbits in the rectangular regions in \( \mathbb{R}_0 \) centered on the special orbits \( \omega_j \) for \( j = 1, 2 \),
\[
\{(r, \pi, z) \in \mathbb{R}_0 \mid |z - (-1)| < \epsilon , \quad 2 \leq r \leq \delta \}
\]
As the value of \( \epsilon > 0 \) tends to 0, the density of such points increases as well, so that one observes the slow entropy of \( G_{2n}^* \) is concentrated in these regions around the special orbits.

Let \( b_1 \geq 1/(\mu_1 \epsilon) \) be such that for all \( \ell \geq b_1 \), for \( j = 1, 2 \), the point \( p_0(j_1; 1, \ell) \) satisfies the estimates in \([178]\).

Choose \( m \geq 1 \), and set \( b_m = m b_1 \). As in Lemma \([21.15]\) let \( b'_m \) be the greatest integer satisfying
\[
b'_m \leq b_m + m L_\delta/\epsilon \leq \{1/\mu_1 + 5/(8\pi \lambda_1)\} \cdot \epsilon .
\]
Let \( k_m \) be the greatest integer for which \( k + 1 \leq m/4 \), then we have the bound \( 2(1+2(k_m+1)) \epsilon/m^2 < \epsilon/m \). So by the recursive procedure above, for \( k \leq k_m \), we can realize the point \( \xi_{(I,J)} = \mathcal{T}_{(I,J)}(\omega_0) \) defined by \([167]\), where there are \( 2^k \) choices of the string \( J = (j_1, \ldots, j_k) \), for a fixed strong \( I = (\ell_1, \ldots, \ell_k) \) satisfying \( \ell_1 \leq b_m \) and \( \ell_i \leq b'_m \) for \( 1 < i \leq k \). Note that such a word has the length estimate
\[
\|\mathcal{T}_{(I,J)}\| \leq k \cdot b'_m \leq b_1 k_m^2/4 .
\]
Recall that \( \epsilon_0 \) was defined in \([168]\).
LEMMA 21.16. For \( n \leq b_1 k^2/4 \) we have \( s(G^n_{\mathcal{M}}, n, \varepsilon_0) \geq 2^k \).

Proof. Let \( J = (j_1, \ldots, j_k) \) and \( J' = (j'_1, \ldots, j'_k) \), and let \( I = I' = (\ell_1, \ldots, \ell_k) \). Suppose that \( J \neq J' \) then let \( 1 \leq \nu \leq k \) be the greatest integer such that \( j_\nu \neq j'_\nu \). Set

\[
\varphi_{(I,J,\nu)} = \psi_{j_\nu} \circ \psi_{j_{\nu-1}} \circ \cdots \circ \psi_{j_1} \circ \psi_{j_0}
\]

where \( \|\varphi_{(I,J,\nu)}\| \leq \|\varphi_{(I,J)}\| \). Assume that \( \xi_{(I,J)} = \varphi_{(I,J)}(\omega_0) \) and \( \xi_{(I,J')} = \varphi_{(I,J')}(\omega_0) \) are defined, then

\[
\begin{align*}
(\varphi_{(I,J,\nu)})^{-1}(\xi_{(I,J)}) &= \tilde{\varphi}_{j_\nu} \circ \psi_{j_{\nu-1}} \circ \cdots \circ \psi_{j_1} \circ \tilde{\varphi}_{j_0} (\omega_0) \\
(\varphi_{(I,J,\nu)})^{-1}(\xi_{(I,J')}) &= \tilde{\varphi}_{j_\nu} \circ \psi_{j_{\nu-1}} \circ \cdots \circ \psi_{j_1} \circ \tilde{\phi}_{j_0} (\omega_0)
\end{align*}
\]

As \( j_\nu \neq j'_\nu \) we have \( d_{\mathcal{M}} ( \varphi_{(I,J,\nu)}^{-1}(\xi_{(I,J)}), \varphi_{(I,J,\nu)}^{-1}(\xi_{(I,J')}) ) \geq \varepsilon_0 \). Thus the collection of points \( \xi_{(I,J)} \) constructed above corresponding to the initial choices of \( \epsilon \) and \( b_1 \) yields a collection of at least \( 2^k \) points which are \((n, \varepsilon_0)\)-separated for \( n \leq b_1 k^2/4 \).

Then by Lemma 21.16 we have for all \( k > 0 \) and \( n \leq b_1 k^2/4 \) the estimate

\[
\frac{\ln(s(G^n_{\mathcal{M}}, n, \varepsilon_0))}{\sqrt{n}} \geq \frac{\ln(2^k)}{\sqrt{b_1 k^2/4}} = \frac{2 \ln(2)}{\sqrt{b_1}}
\]

from which we conclude that \( h_{GLW}^{1/2}(G^n_{\mathcal{M}}) > 0 \), completing the proof of Theorem 21.10.

We conclude this section with two further results concerning the lamination entropy for Kuperberg flows. We only sketch the proofs, which follow the same approach as the proof of Theorem 21.10 above.

THEOREM 21.17. Let \( \Phi_t \) be a generic Kuperberg flow. If the insertion maps \( \sigma_j \) have “fast growth” in the sense of Definition 21.12, then the number \( s(G^n_{\mathcal{M}}, n, \varepsilon_0) \) of \((G^n_{\mathcal{M}}, n, \varepsilon_0)\)-separated points for the \( G^n_{\mathcal{M}} \) action on \( \mathcal{C} \) is asymptotically proportional to \( C \).

Proof. Suppose we are given a finite set \( S_n \subset \mathcal{C} \) of \((G^n_{\mathcal{M}}, n, \varepsilon_0)\)-separated points, and the corresponding subset \( \mathcal{E}_n = p^0_\mathcal{M}(S_n) \subset \mathfrak{M} \) which is \((\tilde{G}_K^n, 2n, \varepsilon_0)\)-separated, as in the proof of Theorem 21.10.

Let \( \xi_1 \neq \xi_2 \in S_n \), and suppose that \( \varphi \in G^n_{\mathcal{M}}(\mathcal{C}) \) satisfies \( d_{\mathcal{M}}(\varphi(\xi_1), \varphi(\xi_2)) \geq \epsilon \). Then set \( \eta_i = p^0_\mathcal{M}(\xi_i) \) and let \( \varphi \in \tilde{G}_K \) be the lifted word which satisfies \( d_{\mathcal{M}}(\varphi(\eta_1), \varphi(\eta_2)) \geq \epsilon' \). For the purposes of the estimates below, we can assume that \( \varphi \in \mathcal{M}(n) \), for \( \mathcal{M}(n) \) as in Definition 14.1 and \( \eta_1, \eta_2 \in \text{Dom}(\varphi) \).

For an analysis of \( \varphi \) as in the proof of Theorem 21.10, we set the offset distances \( \nu_k = 0 \) for all \( k \geq 2 \), so the lower bound estimates on the values \( r_k \) of the \( k \)-th image of the special point \( \omega_0 \) are given by a recursive estimate using the estimates \( 175 \) in Definition 21.12. Start with Lemma 21.13 for some point \( p_\mathcal{M}(j_1, \ell) \) where \( \ell \geq b_0 \). Then apply the fast growth estimate \( 175 \) to obtain a recursive estimate for \( r_{k+1} \) in terms of \( r_k \), which for \( k \geq 3 \) yields

\[
r_k - 2 \geq \lambda^{k-2} (r_2 - 2) \geq \lambda^{k-2} \alpha_\phi/(\mu_2 \ell_1)^2.
\]

Apply the estimate \( 193 \) to \( \varphi \) which is a monotone word ending in \( \phi^+_m \). Assume that \( r(\varphi(\eta_i)) \geq 2 + \delta' \), then \( 2 < r(\eta_i) \leq 2 + (\delta'/\lambda^m) \). Use that \( 0 < \delta' \leq 1 \), then the power \( \ell_1 \) of the initial word \( \varphi \) satisfies

\[
\ell_1 \geq \sqrt{\lambda^{m-2} \alpha_\phi/\mu_2^2 \delta'} \geq (\lambda^{m-2} \alpha_\phi/\mu_2^2
\]

so the power \( \ell_1 \) grows exponentially with \( m \), at the rate approximately \( \lambda^{m/2} \). Thus, to obtain \( 2^m \) words in \( \mathcal{M}(n) \) the length of the first segment \( \psi^{\ell_1} \) must be approximately \( \lambda^{m/2} \), and we obtain the asymptotic estimate on the word length

\[
n \sim m + 1 + \sqrt{1 + \lambda + \lambda^2 + \cdots + \lambda^m} \sim \lambda^{m/2}.
\]

That is, the word length required to obtain an \((n, \varepsilon_0)\)-separated collection of points grows exponentially if the set of points is assumed to grow exponentially.
The work [28, Section 8] of Greg and Krystyna Kuperberg introduces piecewise linear (PL) versions of her flows, and studies properties of their minimal sets. Our last result contributes another insight to the dynamical properties of the piecewise-smooth flows. It is based on a simple observation that if the Wilson flow is allowed to have a discontinuity in its defining vector field \( W \) along the periodic orbits, then we can obtain the opposite conclusion to that of Theorem 21.9. The assumption that the Wilson flow is smooth forces the holonomy of \( \Psi_t \) along the periodic orbits to be unipotent, and the generic Hypothesis [12.2] yields the estimates in Lemma 21.13 which play a fundamental role above. However, for a piecewise-smooth flow \( \Psi \) the derivative of the transverse holonomy of \( \Psi_t \) along the periodic orbits need not equal 1, and in fact can be constructed so that the points \( \omega_i \) are hyperbolic attracting for the map \( \psi \). It is then a long exercise in the methods of the this section to show:

**THEOREM 21.18.** Let \( \Phi_t \) be a Kuperberg flow constructed from a piecewise-smooth Wilson flow \( \Psi_t \) whose holonomy along the periodic orbits is hyperbolic, then \( h_{GLW}(G^{\ast}_{\Phi}) > 0 \).

**Proof.** The proof of Theorem 21.9 constructs collections of \((\varepsilon_0, 2n)\)-separated points for the action of the augmented pseudogroup \( G^*_K \) on \( \mathcal{C}^r \). If the map \( \psi \in G^*_K \) has hyperbolic attracting points \( \omega_i \) for \( i = 1, 2 \), then the estimate (178) becomes exponential, which implies that the number of insertions \( \phi_j^+ \) that can be realized grows exponentially fast with the length of the initial word \( \phi_j^\ell \).

The discussion and results of this section suggest two problems to consider.

**QUESTION 21.19.** Suppose that \( \Phi_t \) is a Kuperberg flow with a hyperbolic singularity at the special orbits, as discussed above, so that \( h_{GLW}(G^{\ast}_{\Phi}) > 0 \). Is it also true that \( h_{top}(\Phi_t) > 0 \) for these flows?

It seems likely that a careful consideration of the methods of this section will provide an affirmative answer to the above question. The second problem is in regards to the calculations used in the proof of Theorem 21.10.

**QUESTION 21.20.** Let \( \Phi_t \) be a generic Kuperberg flow. If the insertion maps \( \sigma_j \) have “slow growth” in the sense of Definition 21.11, does the flow \( \Phi_t \) have slow entropy \( h_{top}^{1/2}(\Phi_t) > 0 \)?

## 22. Growth of leaves

In this section, we study the growth type of the surface \( \mathcal{M}_0 \) considered as a leaf in \( \mathcal{M} \). The growth type is a natural invariant of the flow \( \Phi_t \), and we will show is closely related to the slow entropy of the pseudo\-group \( G^{\ast}_{\mathcal{M}} \) introduced in the previous section. This provides a result analogous to Manning’s Theorem in [31], that the volume growth rate of the universal cover for a compact manifold \( M \) with negative sectional curvature is related to the entropy of the geodesic flow for \( M \).

The idea is to use the construction of the tree \( T_\Phi \) in Section 14, the action of \( G^{\ast}_{\mathcal{M}} \) on \( \mathcal{C}_0 \) and the geometry of \( \mathcal{M}_0 \) as discussed previously in Sections 14, 18 and 21 to calculate the volume growth function of \( \mathcal{M}_0 \) which is defined as follows.

The smoothly embedded zippered lamination \( \mathcal{M} \subset \mathcal{K} \) inherits a Riemannian metric from \( \mathcal{K} \), and we let \( d_{\mathcal{M}} \) denote the induced distance function on the leaves of \( \mathcal{M} \). The submanifold \( \mathcal{M}_0 \subset \mathcal{K} \) with boundary is given this distance function, and we let \( B_{\omega_0}(s) = \{ x \in \mathcal{M}_0 | \ d_{\mathcal{M}}(\omega_0, x) \leq s \} \) be the closed ball of radius \( s \) about the basepoint \( \omega_0 = (2, \pi, 0) = \mathcal{R} \cap \mathcal{T} \). Let \( \text{Area}(X) \) denote the Riemannian area of a Borel subset \( X \subset \mathcal{M}_0 \). Then \( \text{Gr}(\mathcal{M}_0, s) = \text{Area}(B_{\omega_0}(s)) \) is called the growth function of \( \mathcal{M}_0 \).

Given functions \( f_1, f_2: [0, \infty) \to [0, \infty) \) say that \( f_1 \leq f_2 \) if there exists constants \( A, B, C > 0 \) such that for all \( s \geq 0 \), we have that \( f_2(s) \leq A \cdot f_1(B \cdot s) + C \). Say that \( f_1 \sim f_2 \) if both \( f_1 \leq f_2 \) and \( f_2 \leq f_1 \) hold. This defines equivalence relation on functions, which defines their growth type.

The growth function \( \text{Gr}(\mathcal{M}_0, s) \) for \( \mathcal{M}_0 \) depends upon the choice of Riemannian metric on \( \mathcal{K} \) and basepoint \( \omega_0 \in \mathcal{M}_0 \), however the growth type \( [\text{Gr}(\mathcal{M}_0, s)] \) is independent of these choices, as observed by Milnor [32] for coverings of compact manifolds and Plante [41] for leaves of foliations.
We say that \( \mathcal{M}_0 \) has exponential growth type if \( \text{Gr}(\mathcal{M}_0, s) \sim \exp(s) \). Note that \( \exp(\lambda s) \sim \exp(s) \) for any \( \lambda > 0 \), so there is only one growth class of “exponential type”. We say that \( \mathcal{M}_0 \) has nonexponential growth type if \( \text{Gr}(\mathcal{M}_0, s) \lesssim \exp(s) \) but \( \exp(s) \not\lesssim \text{Gr}(\mathcal{M}_0, s) \). We also have the subclass of nonexponential growth type, where \( \mathcal{M}_0 \) has quasi-polynomial growth type if there exists \( d \geq 0 \) such that \( \text{Gr}(\mathcal{M}_0, s) \lesssim s^d \). The growth type of a leaf of a foliation or lamination is an entropy-type invariant of its dynamics, as discussed in [21].

Here is the main result of this section:

**Theorem 22.1.** Let \( \Phi_t \) be a generic Kuperberg flow. If the insertion maps \( \sigma_j \) have “slow growth” in the sense of Definition 21.11, then the growth type of \( \mathcal{M}_0 \) is nonexponential, and satisfies

\[
\exp(\sqrt{s}) \lesssim \text{Gr}(\mathcal{M}_0, s) \lesssim \exp(s)
\]

In particular, \( \mathcal{M}_0 \) does not have quasi-polynomial growth type.

**Proof.** The proof of this result occupies the rest of this section. The first step is to elaborate on the relation between the geometry of the tree \( T_\Phi \) and action of \( G^*_0 \).

Consider the monoid \( \mathcal{M}_G(\infty) \) of monotone words in \( G^*_0 \) as defined in Definition 21.5. The Cayley graph of \( \mathcal{M}_G(\infty) \), denoted by \( |\mathcal{M}_G| \), is the graph with:

1. Vertices given by the set \( \{ \varphi(\omega_0) \mid \varphi \in \mathcal{M}_G(\infty) \} \), and
2. Edges given by the actions of the maps \( \{ \overline{\varphi} \circ \varphi, \overline{\varphi}_1 \circ \varphi, \overline{\varphi}_2 \circ \varphi \} \) on the vertices.

To be more precise, for \( i = 1, 2 \), there is an edge \( \langle \overline{\varphi}_i, \omega_0 \rangle \) joining \( \omega_0 \) to the vertex \( \overline{\varphi}_i(\omega_0) \). For \( \varphi \in \mathcal{M}_G(n) \) suppose that \( \overline{\varphi} \circ \varphi \in \mathcal{M}_G(n+1) \) then we have an edge \( \langle \overline{\varphi} \circ \varphi(\omega_0) \rangle \) joining \( \varphi(\omega_0) \) to \( \overline{\varphi} \circ \varphi(\omega_0) \). For \( \varphi \in \mathcal{M}_G(n) \) and \( i = 1, 2 \) suppose that \( \varphi \circ \overline{\varphi} \in \mathcal{M}_G(n+1) \) then we have an edge \( \langle \varphi, \varphi(\omega_0) \rangle \) joining \( \varphi(\omega_0) \) to \( \varphi \circ \varphi(\omega_0) \).

All edges of \( |\mathcal{M}_G| \) are assigned length 1 with the standard metric on each, so \( |\mathcal{M}_G| \) becomes a complete metric space. Moreover, each vertex \( \varphi(\omega_0) \) has valence equal to one plus the number of words in \( \{ \overline{\varphi} \circ \varphi, \overline{\varphi}_1 \circ \varphi, \overline{\varphi}_2 \circ \varphi \} \) which are well-defined at \( \omega_0 \).

We compare the geometry of the graph \( |\mathcal{M}_G| \) with that of the tree \( T_\Phi \) introduced in Section 14 and that of the manifold \( \mathcal{M}_0 \), using the following standard notion:

**Definition 22.2.** A map \( f : X \to Y \) between metric spaces \( (X, d_X) \) and \( (Y, d_Y) \) is a quasi-isometry if there exists constants \( C_f \geq 0 \) and \( \lambda_f \geq 1 \) so that for all \( x, x' \in X \) we have

\[
\lambda_f^{-1} \cdot d_Y(f(x), f(x')) - C_f \leq d_X(x, x') \leq \lambda_f \cdot d_Y(f(x), f(x')) + C_f.
\]

Moreover, for all \( y \in Y \) there exists \( x \in X \) such that \( d_Y(y, f(x)) \leq C_f \).

The first comparison is a consequence of our previous observations.

**Proposition 22.3.** There is an embedding \( \overline{\Phi} : |\mathcal{M}_G| \to T_\Phi \) which is a quasi-isometry.

**Proof.** Define \( \overline{\Phi} \) as follows. The special vertex point \( \omega_0 \) is sent to basepoint \( \omega_0 \in T_\Phi \) which is pictured in Figure 29. The map \( \overline{\Phi} \) is mapped to the points of \( T_\Phi \) defined by the intersection with \( \mathcal{T} \) of the curve in \( R_0 \) defined by the action of \( \varphi \) on \( \omega_0 \). For \( \varphi \) a generator of \( G^*_0 \), the edge \( \langle \varphi, \varphi(\omega_0) \rangle \) of \( |\mathcal{M}_G| \) is mapped by a constant speed curve to the corresponding branch of \( T_\Phi \subset \mathcal{M}_0 \) connecting the points \( \varphi(\omega_0) \) and \( \varphi \circ \varphi(\omega_0) \) that belong to \( \mathcal{C}_0 \). We give a uniform estimate on the lengths of these branches of \( T_\Phi \).

**Lemma 22.4.** There exists \( 0 < L_1 < L_2 \) such that for each \( \xi, \xi' \in \mathcal{C}_0 \) which are related by the action of a generator \( \{ \varphi, \varphi_1, \varphi_2 \} \) of \( G^*_0 \), the segment \( [\xi, \xi'] \) of the tree \( T_\Phi \subset \mathcal{M}_0 \) joining them has length satisfying \( L_1 \leq L([\xi, \xi']) \leq L_2 \).

**Proof.** For the case when \( \xi' = \overline{\varphi}(\xi) \), it was observed that \( 4\pi \leq L([\xi, \xi']) \leq 6\pi \). Thus, we need consider the case when \( \xi' = \overline{\varphi}_k(\xi) \) for \( k = 1, 2 \). Each point \( \xi \in \mathcal{C}_0 \) is joined to the endpoints \( \{ p_0(\xi), p_0(\xi') \} \) of the \( \gamma_0 \) or
Let $L > 0$ be the upper bound and $L' > 0$ be the lower bound.

Taking $L_1 = \min\{L, 4\pi\}$ and $L_2 = \max\{L', 6\pi\}$, the claim follows. \hfill \qed

To complete the proof of Proposition 22.3 note that Lemma 22.4 shows the edges of $T_\Phi$ have lengths which are uniformly bounded above and below, which implies that $\hat{\Phi}$ is a quasi-isometry. \hfill \qed

The proof of Theorem 19.1 shows that every point of $\mathcal{M}_0$ is a uniformly bounded distance from a point of $T_\Phi$. Thus, $\mathcal{C}_0$ is a net in $\mathcal{M}_0$, which implies:

**Corollary 22.5.** For a generic Kuperberg Plug, the map $\hat{\Phi} : |\mathcal{M}_{\mathcal{M}}| \to \mathcal{M}_0$ obtained from the composition of $\hat{\Phi}$ with the inclusion $T_\Phi \subset \mathcal{M}_0$, is a quasi-isometry. That is, the graph $T_\Phi$ is a “tree model” for the space $\mathcal{M}_0$.

Since, by Corollary 22.5 $|\mathcal{M}_{\mathcal{M}}|$ is quasi-isometric to $\mathcal{M}_0$ we have reduced the study of the growth properties of the leaf $\mathcal{M}_0$ to those of the monoid $\mathcal{M}_{\mathcal{M}}(\infty)$, so by Corollary 21.7 we have:

**Proposition 22.6.** Both $T_\Phi$ and $\mathcal{M}_0$ have subexponential growth rates.

We now return to the proof of Theorem 22.1. By Proposition 22.6 we have $\text{Gr}(\mathcal{M}_0, s) \lesssim \exp(s)$.

To establish the lower bound $\exp(\sqrt{s}) \lesssim \text{Gr}(\mathcal{M}_0, s)$, we assume that $\Phi_t$ is a generic Kuperberg flow whose insertion maps $\sigma_j$ have “slow growth”. Then the proof of Theorem 21.10 constructs a subset of words in $\mathcal{M}_{\mathcal{M}}(\infty)$ whose action on the basepoint $\omega_0 \in T_\Phi$ yields a set of images which grow at the rate $\exp(\sqrt{s})$. In particular, the number of words in $\mathcal{M}_{\mathcal{M}}(\infty)$ must grow at least this rate, which establishes 195. \hfill \qed

## 23. Shape of the minimal set

In this section, we consider the topological properties of the minimal set $\Sigma$ for a generic Kuperberg flow $\Phi_t$. The space $\Sigma$ is compact and connected, so is a continuum, but its definition in terms of the closure of orbits reveals little about its topological nature. The natural framework for the study of topological properties of such spaces is using shape theory. For example, Krystyna Kuperberg posed the question whether $\Sigma$ has stable shape? Stable shape is discussed below, and is about the nicest property one can expect for a minimal set that is not a compact submanifold. Theorem 23.4 below shows that $\Sigma$ does not have stable shape. This result follows almost directly from the homeomorphism between $\Sigma$ and $\mathcal{M}$ for a generic flow, and the structure theory for $\mathcal{M}$ developed in the previous sections of this work. We also investigate additional, much more subtle properties for the shape of the space $\mathcal{M}$, which yields the contrasting results Theorems 23.9 and 23.10 below.

Shape theory studies the topological properties of a topological space $\mathfrak{F}$ using a form of ˇCech homotopy theory. The definition of shape for a space $\mathfrak{F}$ embedded in the Hilbert cube was introduced by Borsuk [3, 5]. Later developments and results of shape theory are discussed in the texts [12, 32] and the historical essay [33]. We give a brief definition of the shape of a compactum $\mathfrak{F}$ embedded in a metric space $X$, following the works of Fox [15], Morita [39] Mardesić [32], and the suggestions of the referee.

**Definition 23.1.** A sequence $\mathfrak{U} = \{U_\ell \mid \ell = 1, 2, \ldots\}$ is called a shape approximation of $\mathfrak{F} \subset X$ if:

1. each $U_\ell$ is an open neighborhood of $\mathfrak{F}$ in $X$ which is homotopy equivalent to a compact polyhedron,
2. $U_{\ell+1} \subset U_\ell$ for $\ell \geq 1$, and $\bigcap_{\ell \geq 1} U_\ell = \mathfrak{F}$.

Suppose that $X, X'$ are connected manifolds, that $\mathfrak{U}$ is a shape approximation for the compact subset $\mathfrak{F} \subset X$, and $\mathfrak{U}'$ is a shape approximation for the compacta subset $\mathfrak{F}' \subset X'$. The compacta $\mathfrak{F}, \mathfrak{F}'$ are said to have the same shape if the following conditions are satisfied:
(1) There is an order-preserving map \( \phi: \mathbb{Z} \to \mathbb{Z} \), and for each \( n \geq 1 \), a continuous map \( f_n: U_{\phi(n)} \to U'_n \) such that for any pair \( n \leq m \), the restriction \( f_n|U_{\phi(m)} \) is homotopic to \( f_m \) as maps from \( U_{\phi(m)} \) to \( U'_m \).

(2) There is an order-preserving map \( \psi: \mathbb{Z} \to \mathbb{Z} \), and for each \( n \geq 1 \), a continuous map \( g_n: U'_{\psi(n)} \to U_n \) such that for any pair \( n \leq m \), the restriction \( g_n|U_{\psi(m)} \) is homotopic to \( g_m \) as maps from \( U_{\psi(m)} \) to \( U_n \).

(3) For each \( n \geq 1 \), there exists \( m \geq \max\{n, \phi \circ \psi(n)\} \) such that the restriction of \( g_n \circ f_{\psi(n)} \) to \( U_m \) is homotopic to the inclusion as maps from \( U_m \) to \( U_n \).

(4) For each \( n \geq 1 \), there exists \( m \geq \max\{n, \psi \circ \phi(n)\} \) such that the restriction of \( f_n \circ g_{\phi(n)} \) to \( U'_m \) is homotopic to the inclusion as maps from \( U'_m \) to \( U'_n \).

**DEFINITION 23.2.** Let \( \mathcal{Z} \subset X \) be a compact subset of a connected manifold \( X \). Then the shape of \( \mathcal{Z} \) is defined to be the equivalence class of a shape approximation of \( \mathcal{Z} \) as above.

It is a basic fact of shape theory that this definition does not depend upon the choice of shape approximations, and that two homotopic compacta have the same shape. The references [12, 32] give complete details and alternate approaches to defining the shape of a space. A concise overview of some of the key aspects of shape theory for continua embedded in Riemannian manifolds is given in [9, Section 2].

For the purposes of this work, we consider the case where \( X \) is a connected compact Riemannian manifold, and \( \mathcal{Z} \subset X \) is an embedded continuum with the induced metric from that on \( X \). The shape of \( \mathcal{Z} \) can then be defined using a shape approximation \( \mathcal{U} \) defined by a descending chain of open \( \epsilon \)-neighborhoods of \( \mathcal{Z} \) in \( X \), given by \( U_\ell = \{ x \in X \mid d_X(x, \mathcal{Z}) < \epsilon_\ell \} \) where we have \( 0 < \epsilon_{\ell+1} < \epsilon_\ell \) for all \( \ell \geq 1 \), and \( \lim_{\ell \to \infty} \epsilon_\ell = 0 \).

We now recall the definition of the stable shape property mentioned above.

**DEFINITION 23.3.** A compactum \( \mathcal{Z} \) has stable shape if it is shape equivalent to a finite polyhedron. That is, there exists a shape approximation \( \mathcal{U} \) such that each inclusion \( i_\ell: U_{\ell+1} \hookrightarrow U_\ell \) induces a homotopy equivalence, and \( U_1 \) has the homotopy type of a finite polyhedron.

Some examples of spaces with stable shape are compact manifolds, and more generally finite CW-complexes. A less obvious example is the minimal set for a Denjoy flow on \( \mathbb{T}^2 \) whose shape is equivalent to the wedge of two circles. In particular, the minimal sets of the aperiodic \( C^1 \)-flows on plugs constructed by Schweitzer in [14] have stable shape. A result of Krasinkiewicz shows that a continuum embedded in a closed orientable surface is either shape equivalent to a finite wedge of circles, or is movable as defined below, and has the shape of a “Hawaiian earring” [20, 30]. In higher dimensions, Clark and Hunton show in [9] that for an \( n \)-dimensional lamination \( \mathcal{Z} \) embedded in an \((n+1)\)-dimensional manifold \( M \) such that \( \mathcal{Z} \) is an attractor for a smooth diffeomorphism \( f: M \to M \), and for which the restriction \( f: \mathcal{Z} \to \mathcal{Z} \) is an expanding map on the leaves of \( \mathcal{Z} \), then \( \mathcal{Z} \) has stable shape. In contrast, the results of the previous sections imply that the shape properties of the minimal set for a generic Kuperberg flow is not so simple. The first result is the following.

**THEOREM 23.4.** The minimal set \( \Sigma \) of a generic Kuperberg flow does not have stable shape.

We begin the proof of this result after some further discussions of the shape properties of \( \mathcal{M} \).

**DEFINITION 23.5.** A compactum \( \mathcal{Z} \subset X \) is said to be movable in \( X \) if for every neighborhood \( U \) of \( \mathcal{Z} \), there exists a neighborhood \( U_0 \subset U \) of \( \mathcal{Z} \) such that, for every neighborhood \( W \subset U_0 \) of \( \mathcal{Z} \), there is a continuous map \( \varphi: U_0 \times [0,1] \to U \) satisfying the condition \( \varphi(x,0) = x \) and \( \varphi(x,1) \in W \) for every point \( x \in U_0 \).

The notion of a movable compactum was introduced by Borsuk [4], as a generalization of spaces having the shape of ANR’s, and is an invariant of shape. See [9, 12, 32] for further discussions concerning movability. It is a standard result that a compactum \( \mathcal{Z} \) with stable shape is movable. The movable property distinguishes between the shape of a Hawaiian earring and a Vietoris solenoid; the former is movable and the latter is not. It is a more subtle problem to construct compacta which are invariant sets for dynamical systems, which are movable but do not have stable shape, such as given in [47].

It is also useful to introduce the pointed movable property:
DEFINITION 23.6. Let \( Z \subset X \) be a continuum with base point \( z_0 \in Z \). We say that \( Z \) is pointed movable in \( X \) if for every neighborhood \( U \) of \( Z \), there exists a neighborhood \( U_0 \subset U \) of \( Z \) such that, for every neighborhood \( W \subset U_0 \) of \( Z \), there is a continuous map \( \varphi : U_0 \times [0, 1] \to U \) satisfying the conditions

- \( \varphi(z_0, t) = z_0 \) for all \( 0 \leq t \leq 1 \);
- \( \varphi(x, 0) = x \) and \( \varphi(x, 1) \in W \) for every point \( x \in U_0 \).

It is apparently unknown at present whether a compacta with movable shape must be pointed movable. The movable and pointed movable properties require the construction of a homotopy retract \( \varphi \) with the properties stated in the definition, whose existence can be difficult to achieve in practice. There is an alternate condition which provides a simple test to show that a compactum \( Z \) is not movable. This follows from the following results:

PROPOSITION 23.7. Let \( Z \) be a movable compacta with shape approximation \( \mathcal{U} \). Then the homology groups satisfy the Mittag-Leffler Condition: For all \( \ell \geq 1 \), there exists \( p \geq \ell \) such that for any \( q \geq p \), the maps on homology groups for \( m \geq 1 \) induced by the inclusion maps satisfy

\[
\text{Image} \{ H_m(U_p; \mathbb{Z}) \to H_m(U_q; \mathbb{Z}) \} = \text{Image} \{ H_m(U_q; \mathbb{Z}) \to H_m(U_p; \mathbb{Z}) \}. \tag{196}
\]

PROPOSITION 23.8. Let \( Z \) be a pointed movable compacta with base point \( z_0 \in Z \) and shape approximation \( \mathcal{U} \). Then the homotopy groups satisfy the Mittag-Leffler Condition: For all \( \ell \geq 1 \), there exists \( p \geq \ell \) such that for any \( q \geq p \), the maps on homotopy groups induced by the inclusion maps satisfy for \( m \geq 1 \),

\[
\text{Image} \{ \pi_m(U_p; z_0) \to \pi_m(U_q; z_0) \} = \text{Image} \{ \pi_m(U_q; z_0) \to \pi_m(U_p; z_0) \}. \tag{197}
\]

These results are special cases of a more general Mittag-Leffler condition, as discussed in detail in [9]. For example, the above forms of the Mittag-Leffler condition can be used to show that the Vietoris solenoid formed from the inverse limit of coverings of the circle is not movable, and is not pointed movable.

We can now state two additional shape properties for the minimal set of a generic Kuperberg flow. First, consider the Mittag-Leffler condition for homology groups.

THEOREM 23.9. Let \( \Sigma \) be the minimal set for a generic Kuperberg flow. Then the Mittag-Leffler condition for homology groups is satisfied. That is, given a shape approximation \( \mathcal{U} = \{ U_\ell \} \) for \( \Sigma \), then for any \( \ell \geq 1 \) there exists \( p > \ell \) such that for any \( q \geq p \)

\[
\text{Image} \{ H_1(U_p; \mathbb{Z}) \to H_1(U_q; \mathbb{Z}) \} = \text{Image} \{ H_1(U_q; \mathbb{Z}) \to H_1(U_p; \mathbb{Z}) \}. \tag{198}
\]

In the proof of Theorem 23.9, the homology classes are represented by closed loops in the appropriate spaces \( U_\ell \), and it is shown that these loops can be homotoped to different levels in the approximation \( U_q \). The details are presented later, but the key point is that the homotopies constructed are not pointed maps. In fact, in contrast to the above result, we also have:

THEOREM 23.10. Let \( \Sigma \) be the minimal set for a generic Kuperberg flow. Then the Mittag-Leffler condition for fundamental groups does not hold for \( \Sigma \).

COROLLARY 23.11. The minimal set \( \Sigma \) of a generic Kuperberg flow is not pointed movable in \( K \).

The proofs of Theorems 23.4, 23.9 and 23.10 follow from the construction of a well-chosen shape approximation for \( \Sigma \), which uses the properties of the level function as developed in Sections 10, 12 and 13. We first make some observations. Theorem 17.1 implies that \( \Omega = \mathcal{M} \) for a generic flow, and thus we analyze the shape properties of \( \mathcal{M} \). As \( \mathcal{M} \) is the closure of \( \mathcal{M}_0 \), we have \( U_\ell(\mathcal{M}, \epsilon) \subset U_\ell(\mathcal{M}_0, \epsilon) \) for all \( 0 < \epsilon < \epsilon' \). Thus, it suffices to consider shape approximations of \( \mathcal{M}_0 \).

Another important point is that \( \mathcal{M}_0 \) retracts to the embedded tree \( T_\Phi \subset \mathcal{M}_0 \) defined in Section 14 and illustrated in Figure 36. We show in Proposition 23.21 that there is a shape approximation \( \{ U_k \mid k > 0 \} \) for \( \mathcal{M}_0 \) for which each set \( U_k \) is an open neighborhood of a compact set \( \mathcal{M}_0 \) which is homotopy equivalent to a 1-dimensional complex formed by taking with quotients of \( T_\Phi \). Because of this, it suffices to consider the
Mittag-Leffler conditions only for first homology groups and for fundamental groups. The key point is that an open neighborhood of $M_0$ “fuses together” sets of points of the tree $T_0$, so that the shape approximations to $M_k$ are homotopy equivalent to a bouquet of circles formed from paths in $T_0$ that start at $ω_0$ and travel out a branch of $T_0$ until they close up using the identification on $T_0$. The systematic description of the classes that arise in this way invokes the labeling system for the double propellers developed in Section 13 and the corresponding labels for the vertices of $T_0$.

First, to fix notation, for $X \subset K$ and $ε > 0$, set:

- $U_ε(X, ε) = \{x \in K \mid d_ε(x, X) < ε\}$ is the open $ε$-neighborhood of $X$ in $K$;
- $C_ε(X, ε) = \{x \in K \mid d_ε(x, X) ≥ ε\}$ is the closed $ε$-neighborhood of $X$ in $K$.

We now begin the recursive construction of a sequence of compact subsets $N_k \subset K$ for $k ≥ 0$, which will be constructed to satisfy the conditions:

1. $M \subset N_k$ and $N_{k+1} \subset N_k$ for all $k ≥ 0$;
2. $N_k$ is homotopy equivalent to a finite wedge of circles;
3. For all $ε > 0$, there exists $k > 0$ such that $N_k \subset U_ε(M_0, ε)$.

It then follows that sufficiently small open neighborhoods of the sets in the collection $\{N_k \mid k ≥ 0\}$ yield a shape approximation for $M$. Moreover, each $N_k$ is constructed so that the branches of $T_0$ above level $k$ are collapsed in the set $N_k$ to branches at level $k$. This critical property is achieved by introducing the notion of “filled double propellers” at level $k$, which are compact regions in $K$ which contain all the branches of $T_0$ with level at least $k$. This containment property follows from the nesting properties of double propellers, as described in Section 13. Colloquially, these filled propellers can be thought of as a collection of “gloves” which envelop collections of branches of $T_0$ at level greater than $k$, grouping them together at the end of a branch at level $k$. The recursive construction of the sets $N_k$ is made precise in the following. We first define $N_0$ and $N_1$ and establish their properties in detail. For the sets $N_k$ with $k > 1$, we provide successively fewer details, leaving these to the reader, as the proofs follow the same outline as for the case of $N_1$ except as noted.

To begin, set:

\begin{equation}
N_0 = \{x \in K \mid r(x) ≥ 2\} \subset K.
\end{equation}

**Lemma 23.12.** $N_0$ is compact.

**Proof.** The discontinuities of the radius function $r : K → [1, 3]$ are contained in the closed $T_0$ defined by (10). By the formulation (13) of the Radius Inequality, the radius value increases at a point of discontinuity, hence $N_0$ is closed in $K$, and thus is compact. \(\square\)

**Lemma 23.13.** The inclusion $N_0 \subset K$ is a homotopy equivalence, and hence $N_0$ is homotopy equivalent to a bouquet of three circles.

**Proof.** The inclusion $\{x \in W \mid r(x) ≥ 2\} \subset W$ is a homotopy equivalence, with both spaces retracting to the circle $\{x = (2, θ, 0) \mid 0 ≤ θ ≤ 2π\}$. The identification map $τ : W → K$ creates a cross-arc between the circle and itself for each of the insertion maps $σ_i$, as illustrated in Figure 8. Thus, both spaces are homotopy equivalent to the curve in Figure 53 and so are homotopy equivalent to a bouquet of three circles. \(\square\)

We fix notation for the generators of $π_1(N_0, ω_0)$ as identified above. Let $[a]$ be the class defined by the loop starting at $ω_0$ and following the Reeb cylinder around in a counterclockwise direction back to $ω_0$. For $i = 1, 2$, let $[b_i]$ be the class defined by the straight path from $ω_0$ to $ω_i$, then following the cross-arc created by the insertion $σ_i$ and then returning to $ω_0$. Then $π_1(N_0, ω_0)$ is the free group generated by $\{[a], [b_1], [b_2]\}$. Note that the choice of the generators $[b_1]$ and $[b_2]$ have an ambiguity in terms of how the end of the cross-arc is joined to the basepoint $ω_0$ to close the path, and differing choices can result in multiplying by a factor of $[a]$. We make a choice of these connecting paths, and consider the choice fixed in the following.
Next, we consider the construction of $\mathfrak{N}_1$ which introduces the notion of filled double propellers, and also reveals the mechanisms for the change in the topology of the spaces $\mathfrak{N}_k$ as $k$ increases.

Recall the definitions (58) and (59) from Section 13

\[
\Gamma' = \mathcal{C} \cup L_1^- \subset \mathcal{W}, \; \Gamma = \sigma_1^{-1}(\Gamma') \subset L_1^-, \quad \Lambda' = \mathcal{C} \cup L_2^- \subset \mathcal{W}, \; \Lambda = \sigma_2^{-1}(\Lambda') \subset L_2^-.
\]

The filled double propellers at level 1 are defined as follows. Let $L^-(1) \subset L_1^-$ denote the closure of the interior region bounded by $\Gamma$, and $L^-(2) \subset L_2^-$ the closure of interior region bounded by $\Lambda$. Analogously, define $L^+(i)$ in the exit region $L_i^+$ for $i = 1, 2$. The Wilson flow of the curves $\Gamma$ and $\Lambda$ generate the infinite double propellers $P_1, P_2 \subset \mathcal{W}$. Let $D(1) \subset \mathcal{W}$ denote the forward $\Psi_t$-flow of $L^-(1)$. We call $D(1)$ the filled double propeller associated to $\Gamma$. Analogously, let $D(2) \subset \mathcal{W}$ denote the forward $\Psi_t$-flow of $L^-(2)$, then $D(2)$ is the filled double propeller associated to $\Lambda$. Note that $D(1)$ and $D(2)$ are disjoint subsets of $\mathcal{W}$.

Consider the notched Reeb cylinder $\mathcal{R}'$, as illustrated in Figure 18. The filled double propellers in $\mathcal{W}$ do not intersect $\mathcal{R}'$, but they do intersect every neighborhood of it, as the closures of both $D(1)$ and $D(2)$ contain the cylinder $\mathcal{R}$, as discussed in the proof of Proposition 11.2. Also, $\tau(\mathcal{R}') \subset \mathbb{K}$ is the embedded Reeb cylinder, illustrated in Figure 24.[4]

For $\delta > 0$, define the subset of $\mathbb{K}$,

\[
C_+^\delta(\tau(\mathcal{R}'), \delta) = C_+^\delta(\tau(\mathcal{R}'), \delta) \cap \mathfrak{N}_0 = \{x \in \mathbb{K} \mid d_\mathbb{K}(x, \tau(\mathcal{R}')) \leq \delta\} \cap \mathfrak{N}_0.
\]

Then $C_+^\delta(\tau(\mathcal{R}'), \delta)$ is a closed $\delta$-neighborhood of $\tau(\mathcal{R}')$, contained in the compact subset $\mathfrak{N}_0 \subset \mathbb{K}$, hence is compact. Choose $\delta_1$ small enough so that the set $C_+^\delta_1(\tau(\mathcal{R}'), \delta_1)$ retracts to $\tau(\mathcal{R}')$. In terms of the illustration Figure 24, we choose $\delta_1$ less than the distance between the insertions and the edges of the gaps, so that $C_+^\delta_1(\tau(\mathcal{R}'), \delta_1)$ has no “self-intersections”.

For $i = 1, 2$, set $D(i) = \tau(D(i) \cap \mathcal{W}) \subset \mathbb{K}$, where $\mathcal{W}$ is the closure of $\mathcal{W}'$ as defined in Section 4. Then define:

\[
\mathfrak{N}_1 = C_+^\delta_1(\tau(\mathcal{R}'), \delta_1) \cup D(1) \cup D(2).
\]

Thus, $\mathfrak{N}_1$ is obtained by attaching two infinite filled double propellers to $C_+^\delta_1(\tau(\mathcal{R}'), \delta_1)$.

**Lemma 23.14.** $\mathfrak{N}_1$ is compact.

*Proof.* Consider $\tau^{-1}(C_+^\delta_1(\tau(\mathcal{R}'), \delta_1))$ which is a thickened cylinder. For each $i = 1, 2$, the region $D(i)$ is a connected solid spiral turning around $\mathcal{C}$ an infinite number of times, where after a finite number of turns, with the number of times determined by $\delta_1$, the end of the solid region is contained in $\tau^{-1}(C_+^\delta_1(\tau(\mathcal{R}'), \delta_1))$. Thus, $D(i) - (D(i) \cap \tau^{-1}(C_+^\delta_1(\tau(\mathcal{R}'), \delta_1)))$ has compact closure in $\mathcal{W}$. It follows that $\mathfrak{N}_1$ is the union of the compact set $C_+^\delta_1(\tau(\mathcal{R}'), \delta_1)$ with the images under $\tau$ of compact subsets of $D(1)$ and $D(2)$, hence is compact. □

**Lemma 23.15.** $\mathfrak{M} \subset \mathfrak{N}_1 \subset \mathfrak{N}_0$. 

![Figure 53. Homotopy type of $\mathbb{K}$ and $\mathfrak{N}_0$](image-url)
**Proof.** It was shown in Section 12 that \( \mathcal{M}_0 \) is the ascending union of the sets \( \mathcal{M}_n \) for \( n \geq 0 \), where \( \mathcal{M}_0 \) consists of propellers at level \( n \). By construction, \( \mathcal{R}_1 \) contains the sets \( \mathcal{M}_0 \) and \( \mathcal{M}_1 \). It was observed in Section 13 that all of the \( \Gamma \) and \( \Lambda \) curves at level at least 2 in the face \( \partial^+_n \mathcal{W} \) are contained in the interiors \( L^{-}(i) \) of the parabolic arcs \( \Gamma, \Lambda \subset \partial^+_n \mathcal{W} \). Thus, the double propellers with level at least 2 are contained in the filled propellers \( D(1) \) and \( D(2) \), hence \( \mathcal{M}_0 \subset \mathcal{R}_1 \). As \( \mathcal{R}_1 \) is closed, it also contains \( \mathcal{M} \). \( \square \)

**LEMMA 23.16.** For \( \epsilon > 0 \) sufficiently small, \( U(\mathcal{R}_1, \epsilon) \) retracts to \( \mathcal{R}_1 \).

**Proof.** The proof of Lemma 23.14 shows that \( \mathcal{R}_1 \) is the union of three compact submanifolds with boundary with corners. Hence, \( \mathcal{R}_1 \) is a submanifold with boundary with corners, from which the conclusion follows. \( \square \)

**LEMMA 23.17.** \( \mathcal{R}_1 \) has the homotopy type of a finite wedge of circles.

**Proof.** For each \( i = 1, 2 \), attaching \( D(i) \) to \( \tau^{-1}(C^+_K(\tau(\mathcal{R}'), \delta_1)) \) is homotopy equivalent to attaching one endpoint of a line segment to the core circle of the cylinder \( \mathcal{R} \). For the image \( D(i) \subset \mathbb{K} \) the other endpoint of the segment is attached to \( C^+_K(\tau(\mathcal{R}'), \delta_1) \), resulting in a space with the same homotopy type as \( \mathcal{M}_0 \). However, there are additional “handles” formed in the image which are not as immediate to visualize. These result from the intersections of the images \( D(i) \) for \( i = 1, 2 \) with themselves. That is, while the filled double propellers \( D(1), D(2) \subset \mathcal{W} \) are disjoint from each other, their images \( D(1) \) and \( D(2) \) in \( \mathbb{K} \) under the quotient map \( \tau : \mathcal{W} \to \mathbb{K} \) are not disjoint, and this gives rise to additional 1-cycles in \( \mathcal{R}_1 \). The loops created by these self intersections are called *exceptional cycles*. While the number of intersections in \( \mathbb{K} \) of the filled propellers with themselves will generate an infinite number of homotopy classes of loops, there are at most finitely many homotopy classes of exceptional cycles outside of \( C^+_K(\tau(\mathcal{R}'), \delta_1) \). It follows that \( \mathcal{R}_1 \) has the homotopy type of a finite wedge of circles. \( \square \)

Note that the inclusion \( \mathcal{R}_1 \subset \mathcal{M}_0 \) induces an inclusion map of free groups,

\[
i_1 : \pi_1(\mathcal{R}_1, \omega_0) \to \pi_1(\mathcal{M}_0, \omega_0) \cong \langle [a], [b_1], [b_2] \rangle.
\]

Thus, each element of \( \pi_1(\mathcal{R}_1, \omega_0) \) has a unique reduced expression as a word in the generators \( \{ [a], [b_1], [b_2] \} \).

We next describe in more detail the classes in the image of the map \( i_1 \), and in particular the exceptional cycles introduced in the proof of Lemma 23.17 which are generated by intersections and self-intersections of the regions \( D(1) \) and \( D(2) \). We use the labeling of the double propellers from Sections 12 and 13 to index the intersections of these filled propellers. Recall that \( D(1) \) is the interior region of the infinite double propeller \( \tau(P'_1) \), and the propeller \( P_1 \subset \mathcal{W} \) intersects \( \mathcal{L}^-_1 \) along the curves \( \Gamma'(i, \ell) \) for \( i = 1, 2 \) and \( \ell \geq b \), with \( b \) as defined in Section 13. Analogous observations apply for \( D(2) \) and the infinite double propeller \( \tau(P'_2) \). The curves \( \Gamma' \) and \( \Lambda' \) at levels 1 and 2 are illustrated in Figure 30.

Let \( L^{-}(1; i, \ell) \subset L^-_1 \) be the compact region bounded by \( \Gamma(i, \ell) = \sigma^{-1}_i(\Gamma'(i, \ell)) \). For the exit regions, we have the analogous compact regions \( L^+(1; i, \ell) \subset L^+_1 \). For \( \Lambda \)-curves, we have the analogous entry and exit compact regions \( L^+(2; i, \ell) \subset L^+_1 \).

Consider their images under the map \( \tau : \mathcal{W} \to \mathbb{K} \) which identifies \( L^+_1 \) and \( L^-_1 \) with the secondary entry and secondary exit regions. We now analyze the intersections and self-intersections that are created. For \( i_0, i_1 = 1, 2 \), the regions \( \tau(L^{-}(i_0; i_1, \ell)) \subset D(i_0) \) are the components of the set \( D(i_0) \cap E_{i_1} \), so by the nesting property of \( \Gamma \) and \( \Lambda \) curves, we have that:

- \( \tau(L^+(1; 1, \ell)) \subset \tau(L^+(1)) \) and thus is contained in \( D(1) \);
- \( \tau(L^+(1; 2, \ell)) \subset \tau(L^+(2)) \) and thus is contained in \( D(2) \).

Analogously, we have:

- \( \tau(L^+(2; 1, \ell)) \subset \tau(L^+(1)) \) and thus is contained in \( D(1) \);
- \( \tau(L^+(2; 2, \ell)) \subset \tau(L^+(2)) \) and thus is contained in \( D(2) \).

Thus, \( D(1) \cap D(2) \) consists of the regions:
• \( \tau(L^\pm(1; 2; \ell)) \subset E_2 \cup S_2 \), for \( \ell \geq b \) and unbounded;
• \( \tau(L^\pm(2; 1; \ell)) \subset E_1 \cup S_1 \), for \( \ell \geq b \) and unbounded.

Also, note that \( \tau(L^\pm(i_0; i_1; \ell)) \) retracts to \( C^{+}_i(\tau(R'), \delta_1) \) in \( C^{+}_i(\tau(R'), \delta_1) \) for \( \ell \geq \ell(\delta_1) \), where the index \( \ell(\delta_1) \) tends to infinity as \( \delta_1 \) tends to zero. It follows that the number of such regions which are not retractable in \( C^{+}_i(\tau(R'), \delta_1) \) to the core \( C^{+}_i(\tau(R'), \delta_1) \) is finite, and bounded above by \( a + \ell(\delta_1) \).

Next, we describe classes in \( \pi_1(\mathcal{M}_0, \omega) \) that are the images of classes in \( \pi_1(\mathcal{N}_1, \omega_0) \) which result from the above constructions. Such a class is represented by a continuous path \( \sigma: [0, 1] \to \mathcal{M}_0 \) with endpoints \( \omega_0 \). The path \( \sigma \) can also be considered as a path \( \sigma': [0, 1] \to \mathfrak{T}_\Phi \subset \mathcal{M}_0 \) with a finite number of discontinuities, which are connected by jumps, that is (short) paths in \( \mathcal{M}_1 = \mathcal{M}_0 \). There are three cases to consider.

First, suppose the path \( \sigma \) never enters one of the propellers attached to the Reeb cylinder. Then \( \sigma \) must be continuous, and is endpoint-fixed homotopic to a path which goes around the Reeb cylinder \( R' \) an integer \( m \) number of times, where \( m > 0 \) indicates a counter-clockwise direction around the cylinder and \( m < 0 \) a clockwise direction. It then closes up at \( \omega_0 \) again. That is, the path follows the base loop in \( \mathfrak{T}_\Phi \), as illustrated by the horizontal line in Figure 36, and corresponds to the action of \( \bar{\psi}^m \) on the basepoint \( \omega_0 \) in \( \mathfrak{T}_\Phi \) as described in (65) of Section 14. The image of the cycle in \( \pi_1(\mathcal{M}_0, \omega_0) \) is thus \([a]^m\).

In the second case, suppose the path \( \sigma \) goes from \( \omega_0 \) in the cylinder \( R' \) to one of the points \( \omega_i \) for \( i = 1, 2 \), then enters the corresponding propeller of \( \mathcal{M}_0 \), as illustrated in Figure 36. Then we can assume that the initial segment of \( \sigma \) is contained in \( \mathfrak{T}_\Phi \) and goes from \( \omega_0 \) to either \( \phi_1(\omega_0) \) or \( \phi_2(\omega_0) \) in the lower or upper branch in Figure 36 respectively. This initial segment of the path is homotopic to the generator \([b_i]\), for \( i = 1, 2 \). If the path then continues along the corresponding branch of \( \mathfrak{T}_\Phi \) without entering through another insertion face, it must proceed along the branch until it contains a point in \( C^{+}_i(\tau(R'), \delta_1) \). It then follows a short path in \( C^{+}_i(\tau(R'), \delta_1) \) back to the Reeb cylinder \( R' \), where it continues so that it closes up at \( \omega_0 \). The segment of the path after entering the propeller is homotopic to some multiple of the class \([a]^m\) in \( \mathcal{M}_0 \), where \( m \) depends on the length of the propeller of the path. The resulting class in \( \pi_1(\mathcal{N}_1, \omega_0) \) has image \([a]^m \cdot [b_i]\), and is called a cycle of type (2). The least integer \( m \) so that the path \( \sigma \) can be connected to \( \omega_0 \) as its terminal point depends on the length of the path in the level 1 propeller, and so depends on the choice of \( \delta_1 > 0 \).

Note that there is another related way to construct classes in \( \pi_1(\mathcal{N}_1, \omega_0) \) using the insertion maps, where the path \( \sigma \) goes from \( \omega_0 \) in the cylinder \( R' \) to one of the points \( \omega_i \) for \( i = 1, 2 \), then enters the corresponding propeller of \( \mathcal{M}_0 \). The path then follows a path from the entry face \( L^-_i \) to the exit face \( L^+_i \), and then along a path back to \( \omega_0 \). It may happen that the path in the propeller from the entry face to the exit face turns at least once around the Reeb cylinder \( R' \), so that the class in \( \pi_1(\mathcal{M}_0, \omega_0) \) that it yields is \([b_i]^{-1} \cdot [a]^\ell \cdot [b_i]\), which if \( \ell \neq 0 \) is non-trivial. However, this cycle is homotopic in \( \mathcal{M}_1 \) to a cycle which is the product of a type (2) cycle and the inverse of a type (2) cycle. Thus, the class it determines in \( \pi_1(\mathcal{N}_1, \omega_0) \) equals a product of factors which were constructed above,

\[
[b_i]^{-1} \cdot [a]^m \cdot [b_i] = ([a]^m \cdot [b_i])^{-1} \cdot [a]^\ell \cdot ([a]^m \cdot [b_i]).
\]

Thus, such a cycle does not contribute an additional generator to the group \( \pi_1(\mathcal{N}_1, \omega_0) \).

In the third case, the existence of the cycles we construct is less obvious than for the previous two cases, the exceptional cycles. Again, suppose an initial segment \( \sigma' \) of the path \( \sigma \) goes from \( \omega_0 \) along \( \mathfrak{T}_\Phi \) to a point \( \bar{\psi}^i \circ \phi_{i_1}(\omega_0) \), for \( i_1 = 1, 2 \) and \( \ell \geq b \). Recall that \( p_0^i(\bar{\psi}^i \circ \phi_{i_1}(\omega_0)) \) is the lower or upper endpoint of the curve containing \( \bar{\psi}^i \circ \phi_{i_1}(\omega_0) \). The positive \( K \)-orbit of such a point hits \( E_{i_0} \). Then let \( \sigma'' \) be a path which starts at \( p_0^i(\bar{\psi}^i \circ \phi_{i_1}(\omega_0)) \) and then enters a level 2 propeller through a face \( E_{i_0} \). After entering this level 2 propeller it then continues along the level 2 propeller until it reaches the point \( \bar{\psi}^i_{i_0} \circ \phi_{i_1}(\omega_0) \in \mathcal{R}_0 \) which is also contained in \( \mathcal{D}(i_0) \), and is then connected in the filled propeller back to \( \phi_{i_1}(\omega_0) \). The path \( \sigma \) then follows the edges of \( \mathfrak{T}_\Phi \) back to \( \omega_0 \). The concatenation of these paths yields the loop \( \sigma \), which defines a
class in $\pi_1(\mathcal{N}_1, \omega_0)$ whose image in $\pi_1(\mathcal{N}_0, \omega_0)$ has the form

$$[b_{i_0}]^{-1} \cdot [b_{i_0}] \cdot ([a]^{m_1} \cdot [b_{i_1}])$$

for any $m_1 \geq b$. Observe that in $\pi_1(\mathcal{N}_1, \omega_0)$ the two left hand factors do not cancel. By changing the notation for components of the filled double propellers at level 1-sided neighborhood of the space $\mathcal{N}_1$ to level $\mathcal{N}_0$ we obtain elements of $\pi_1(\mathcal{N}_0, \omega_0)$ whose image in $\pi_1(\mathcal{N}_0, \omega_0)$ has the form

$$[b_{i_0}]^{-1} \cdot ([a]^{m_2} \cdot [b_{i_0}]) \cdot ([a]^{m_1} \cdot [b_{i_1}])$$

for $m_1 \geq b$ and $m_2 \geq 0$.

Note that if $m_1$ is sufficiently large, then this exceptional cycle is homotopic in $\mathcal{N}_1$ to a product of cycles of type (2) as defined previously. Thus, the number of additional generators of $\pi_1(\mathcal{N}_1, \omega_0)$ formed by the exceptional cycles is bounded above by a number depending on $\delta_1$, where the number increases as $\delta_1$ decreases, since a smaller value of $\delta_1 > 0$ uncovers an increasing number of level 1 propellers and so a larger value for $m_1$ is allowed.

Note that if the filled regions $D(i)$ in $\mathcal{N}_1$ are replaced by the propellers $P_\gamma$ and $P_\lambda$, then the classes in $\pi_1(\mathcal{N}_0, \omega_0)$ represented by exceptional cycles are no longer defined, as the segment connecting $\phi_{i_0} \circ \psi^d \circ \phi_{i_1}(\omega_0)$ to $\phi_{i_2}(\omega_0)$ in the region $D(i_0)$, no longer exists. In particular, exceptional cycles of the form (202) no longer exist for small values of $m_1$ in the set $\mathcal{N}_k$ (as defined below) for $k > 1$.

The construction of the space $\mathcal{N}_k$ for $k > 1$ is analogous to that of $\mathcal{N}_1$. It is defined as a union of a closed 1-sided neighborhood of the space $\mathcal{M}_0^{k-1}$ with the filled double propellers at level $k$. Note that the filled double propellers at level $k - 1$ in $\mathcal{N}_{k-1}$ will no longer be contained in $\mathcal{N}_k$, as they are replaced by filled double propellers at level $k$. Again, observe that the inclusion $\mathcal{N}_k \subset \mathcal{N}_0$ induces an inclusion map of free groups,

$$i_k: \pi_1(\mathcal{N}_k, \omega_0) \to \pi_1(\mathcal{N}_0, \omega_0) \cong \langle [a], [b_1], [b_2] \rangle,$$

so that each element of $\pi_1(\mathcal{N}_k, \omega_0)$ has a unique reduced expression as a word in the generators $\{[a], [b_1], [b_2] \}$.

Though it is simple to state the recursive construction of $\mathcal{N}_k$ in outline, the actual construction becomes increasingly complicated to describe for increasing $k$, as it is based on the labeling for components of the filled double propellers given in Section 13, and this labeling system is recursive and grows in complexity as $k$ increases. We discuss this process in further detail for level $k = 2$ below, in order to illustrate the pattern of the recursive construction. The general case for $k \geq 3$ is then only briefly sketched.

We describe the construction and properties of $\mathcal{N}_2$. Recall that the double propellers at level 2 are labeled by their generating curves $\Gamma(i_1, \ell)$ and $\Lambda(i_1, \ell)$ in $L_{i_1}^\ell$ for $i_1 = 1, 2$ and $\ell \geq b$. For each such curve, we define the filled parabola $L^-(i_0; i_1, \ell)$ and the corresponding filled double propeller $D(i_0; i_1, \ell)$ at level 2 is given by the $\Psi_\ell$-flow of $L^-(i_0; i_1, \ell)$. Regarding this notation, if $i_0 = 1$ then the boundary of $D(i_0; i_1, \ell)$ is $\Gamma(i_1, \ell)$, and if $i_0 = 2$ then the boundary of $D(i_0; i_1, \ell)$ is $\Lambda(i_1, \ell)$. As all $\Gamma$ and $\Lambda$ curves which generate these double propellers are contained in the region $\{r > 2\} \subset \partial N \mathbb{W}$, each filled double propeller $D(i_0; i_1, \ell)$ is a compact region in $\mathbb{W}$.

Choose $\delta_2 \leq \delta_1/2$ sufficiently small, so that the one-sided closed $\delta_2$-neighborhood of $\mathcal{M}_0^1$ given by

$$C_\mathcal{K}^+ (\mathcal{M}_0^1, \delta_2) = C_\mathcal{K} (\mathcal{M}_0^1, \delta_2) \cap \mathcal{N}_1$$

does not contain all the level 2 propellers. The exact choice of $\delta_2$ will be specified after some preliminary constructions. Set $D(i_0; i_1, \ell) = \tau (D(i_0; i_1, \ell) \cap \mathbb{W})$ and define

$$\mathcal{N}_2 = C_\mathcal{K}^+ (\mathcal{M}_0^1, \delta_2) \cup \left\{ D(i_0; i_1, \ell) \mid i_0, i_1 = 1, 2 \text{ and } \ell \geq b \right\}.$$

Thus, $\mathcal{N}_2$ is obtained by attaching to the set $C_\mathcal{K}^+ (\mathcal{N}_1, \delta_2)$ a closed 1-sided $\delta_2$-neighborhood of the level 1 propellers to obtain $C_\mathcal{K}^+ (\mathcal{N}_0^1, \delta_2)$, and then attaching the filled double propellers at level 2.
We next state versions of Lemmas 23.15 and 23.16 for \( \mathfrak{M}_2 \) whose proofs follow in the same way.

**Lemma 23.18.** \( \mathfrak{M} \subset \mathfrak{M}_2 \subset \mathfrak{M}_1 \).

**Lemma 23.19.** For \( \epsilon > 0 \) sufficiently small, \( U(\mathfrak{M}_2, \epsilon) \) retracts to \( \mathfrak{M}_2 \).

The description of the homotopy type of \( \mathfrak{M}_2 \) is analogous with the description of \( \mathfrak{M}_1 \) above, and again uses the labeling of the double propellers from Sections 12 and 13. However, in addition to the exceptional cycles in \( \mathfrak{M}_3 \) that arise from the intersections and self-intersections of the filled double propellers at level 2, there is subtlety in the existence “cycles of type (2)” which occur for the spaces \( \mathfrak{M}_k \) when \( k \geq 2 \).

Consider first the existence of exceptional cycles. For \( \ell \) large enough, \( \mathcal{D}(i_0; i_1, \ell) \) intersects the entry region \( E_i \) for \( i = 1, 2 \). The intersection \( \mathcal{D}(i_0; i_1, \ell) \cap E_i \) is the along the region's boundary by the curves \( \tau(\Gamma(i_1, \ell; i_2, \ell')) \) if \( i_0 = 1 \), and \( \tau(\Lambda(i_1, \ell; i_2, \ell')) \) if \( i_0 = 2 \), and \( \ell' \geq b \) and bounded. As before, the regions \( \mathcal{D}(i_0; i_1, \ell) \) are disjoint and contractable in \( \mathbb{W} \), but their images \( \mathcal{D}(i_0; i_1, \ell) \) may have multiple intersections, so they are not necessarily contractible. Let \( \gamma = \frac{b}{\ell_0 \ell_1} > 0 \) be the greatest number such that the attachment of \( \mathcal{D}(i_0; i_1, \ell) \) does not change the homotopy type of \( \mathfrak{M}_2 \) if \( b \leq \ell < \gamma(i_0; i_1) \). Observe that this phenomena is independent of the choice of \( \delta_2 \).

As the filled double propellers \( \mathcal{D}(i_0; i_1, \ell) \) get longer as \( \ell \) increases, there exist constants

\[
(205) \quad \ell(\delta_2;i_0;i_1) > s(\delta_2;i_0;i_1) \geq b
\]

such that, for \( i_0, i_1 = 1, 2 \):

1. For \( b \leq \ell < s(\delta_2;i_0;i_1) \), the filled double propellers \( \mathcal{D}(i_0; i_1, \ell) \subset \mathbb{W} \) and the pre-image \( \tau^{-1}(C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2)) \) are disjoint. If \( \ell < \gamma(i_0; i_1) \), then \( \mathcal{D}(i_0; i_1, \ell) \) is homotopically trivial and the attachment of \( \mathcal{D}(i_0; i_1, \ell) \) to \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \) does not change the homotopy type.

2. For \( s(\delta_2;i_0;i_1) \leq \ell < \ell(\delta_2;i_0;i_1) \), the double filled propellers \( \mathcal{D}(i_0; i_1, \ell) \subset \mathbb{W} \) intersect the set \( \tau^{-1}(C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2)) \) and \( \mathcal{D}(i_0; i_1, \ell) \) does not retract in \( \mathfrak{M}_2 \) to \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \). In this case,

\[
\mathcal{D}(i_0; i_1, \ell) - \left( \mathcal{D}(i_0; i_1, \ell) \cap C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \right)
\]

is a non-empty submanifold with compact closure, and the finite filled double propeller \( \mathcal{D}(i_0; i_1, \ell) \) is such that its base and endpart are in \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \). The attachment of \( \mathcal{D}(i_0; i_1, \ell) \) to \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \) adds a handle, which is said to be of type (2). Each handle of type (2) which is attached increases the rank of the fundamental group.

3. For \( \ell \geq \ell(\delta_2;i_0;i_1) \), the filled double propellers \( \mathcal{D}(i_0; i_1, \ell) \) retract in \( \mathfrak{M}_2 \) to \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \), and thus adding these propellers does not change the homotopy type of \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \).

The proof of the following result is analogous to that of Lemmas 23.14 and 23.17.

**Lemma 23.20.** \( \mathfrak{M}_2 \) is compact and has the homotopy type of a finite wedge of circles.

Next, we explain the condition that “\( 0 < \delta_2 < \delta_1/2 \) is sufficiently small” in the definition (203), and then \( \mathfrak{M}_2 \) is defined using this choice of \( \delta_2 \). The value of \( \delta_2 \) will be specified in terms of the traces of the propellers on \( \mathfrak{R}_0 \), as illustrated in Figure 31.

The trace of \( C_{\mathfrak{M}}^+(\mathfrak{M}_0, \delta_2) \) on \( \mathfrak{R}_0 \) is the 1-sided \( \delta_2 \)-neighborhood of \( \tau(\mathcal{R}') \cap \mathfrak{R}_0 \) and of the curves \( \gamma_0(\ell_1), \lambda_0(\ell_1) \) for \( \ell_1 \geq a \) and unbounded. For \( \ell_1 \geq b \), the trace of \( \mathcal{D}(i_0; i_1, \ell_1) \) is the region bounded by the curves \( \Gamma_0(i_1, \ell_1; \ell_2) \) if \( i_0 = 1 \), and by the curves \( \Lambda_0(i_1, \ell_1; \ell_2) \) if \( i_0 = 2 \), for \( \ell_2 \geq a \) and bounded.

Recall from Section 13 that for \( i_1 \) and \( \ell_2 \) fixed, the curves \( \gamma_0(i_1, \ell_1; \ell_2) \) accumulate as \( \ell_1 \to \infty \), on \( \gamma_0(\ell_2) \) if \( i_1 = 1 \) and on \( \lambda_0(\ell_2) \) if \( i_1 = 2 \). Analogously, the curves \( \Lambda_0(i_1, \ell_1; \ell_2) \) accumulate as \( \ell_1 \to \infty \), on \( \gamma_0(\ell_2) \) if \( i_1 = 1 \) and on \( \lambda_0(\ell_2) \) if \( i_1 = 2 \). Thus, there exists \( \ell(\delta_2;i_0;i_1) \) such that for every \( \ell_1 \geq \ell(\delta_2;i_0;i_1) \), for \( i_0 = 1 \) the curve \( \Gamma_0(i_1, \ell_1; a) \), and for \( i_0 = 2 \) the curve \( \Lambda_0(i_1, \ell_1; a) \), intersects the 1-sided \( \delta_2 \)-neighborhood of \( \gamma_0(a) \cup \lambda_0(a) \).
Note that we might need to take $\ell'(\delta_2; i_0; i_1)$ slightly bigger than $\ell'(\delta_2; i_0; i_1)$ so that case (3) is satisfied: that is, the filled double propeller $D(i_0; i_1; \ell_1) \subset W$ intersects $\tau^{-1}(C^+(\M_0, \delta_2))$ along all its length, and thus $D(i_0; i_1; \ell_1)$ retracts in $\mathcal{N}_2$ to $C^+_{K}(\M_0, \delta_2)$.

We estimate the value of $s(\delta_2; i_0; i_1)$. To simplify the discussion, consider the case $i_0 = 1$. For $\ell_1 < \ell'(\delta_2; 1; i_1)$ and $\delta_2$ small, the curve $\Gamma_0(i_1, \ell_1; a)$ is disjoint from the 1-sided $\delta_2$-neighborhood of $\gamma_0(a) \cup \lambda_0(a)$. Take $\ell_2 = \ell'(\delta_2; i_0; i_1) - 1$, then there exists $\ell_2 > a$ such that $\Gamma_0(i_2, \ell_1; \ell_2)$ intersects the 1-sided $\delta_2$-neighborhood of $\gamma_0(\ell_2) \cup \lambda_0(\ell_2)$. Thus the filled double propeller $D(1; i_1, \ell_1)$ satisfies case (2).

As $\ell_1$ decreases, the filled double propellers $D(1; i_1, \ell_1)$ get shorter, and thus there exists $s'(\delta_2; 1; i_1)$ such that if $\ell_1 < s'(\delta_2; 1; i_1)$, the curves $\Gamma_0(i_1, \ell_1; \ell_2)$ are disjoint from $C^+(\M_0, \delta_2)$ for any $\ell_2 > a$. In the same way we obtain $s'(\delta_2; 2; i_1)$, and hence $s(\delta_2; i_0; i_1) \leq s'(\delta_2; i_0; i_1)$ such that case (1) is satisfied.

Then for $\delta_2$ sufficiently small, case (2) is non-empty. The addition of the propellers $D(i_0; i_1, \ell)$ in case (2) creates new handles: each propeller retracts to its intersection with the annulus $A$, thus an arc whose endpoints are in $C^+(\M_0, \delta_2)$ that is not contained in the previous set. Hence, we add $\sum_{j_0, j_1} \ell(\delta_2; i_0; i_1) - s(\delta_2; i_0; i_1)$ handles representing cycles of type (2) to the homotopy of $\mathcal{N}_2$. Thus, the inclusion $\mathcal{N}_2 \subset \mathcal{N}_1$ is not a homotopy equivalence.

The construction of $\mathcal{N}_2$ has an interpretation in terms of the embedded tree $T_{\Phi} \subset \M_0$. The closed set $\mathcal{N}_2$ defines a closed neighborhood of $\M_0$ and hence of the embedded tree $T_{\Phi} \subset \M_0$. Topologically, this corresponds to two operations: first attaching, at a suitably large distance from the root point $\omega_0$, the ends of the two level 1 branches to $\omega_0$. Second, selecting a finite number, equal to $\sum_{j_0, j_1} \ell(\delta_2; i_0; i_1) - s(\delta_2; i_0; i_1)$, of level 2 branches whose end points get identified to a certain point in the level 1 branches, thus adding this number of loops to the graph. The branches of the tree at higher levels are all collapsed into the filled regions, hence to one of the $D(i_0; i_1; \ell)$.

The classes in $\pi_1(\mathcal{N}_2, \omega_0)$ represented by cycles of type (2) in $\mathcal{N}_2$ at level $\ell$ for $1 \leq \ell \leq 2$. These are given by a closed curve $\sigma$ based at $\omega_0$, which passes through $\ell$ insertion faces up to the arm of a propeller at level $\ell$ which is not contained in the set $C^+(\M_0, \delta_1)$. Then closes up via a path along the propeller at level $\ell$ to a point which lies in $C^+(\M_0, \delta_1)$, and then back to $\omega_0$ by a path in $R'$. These cycles of type (2) define classes in $\pi_1(\mathcal{N}_2, \omega_0)$ whose images in $\pi_1(\mathcal{N}_1, \omega_0)$ have the form, in the case $\ell = 2$,

\begin{equation}
[a]^{m_2} \cdot [b_{i_2}] \cdot [a]^{m_1} \cdot [b_{i_1}] \quad \text{with } i_j = 1, 2 \text{ and } m_i > b.
\end{equation}

We require that $m_1$ and $m_2$ are large enough so that the closed path exists, but not so large that the expression in \cite{206} is a product of generators in $\pi_1(\mathcal{N}_2, \omega_0)$ corresponding to cycles of type (2) at level 1.

Again, note that if the value of $\delta_2$ is replaced by a value $\delta < \delta_2$, the homotopy type of $C^+(\M_0, \delta_2)$ does not change. But the homotopy type of $\mathcal{N}_2$ does change, as the number of homotopically non-trivial handles formed by the attachment of filled double propellers depends on $\delta_2$.

We describe the construction of $\mathcal{N}_3$ next. For $0 < \delta_3 < \delta_2/2$, introduce the one-sided closed $\delta_3$-neighborhood of $\M_0^2$ given by $C^+(\M_0^2, \delta_3) = C^+(\M_0^2, \delta_3) \cap \mathcal{N}_2$. Choose $\delta_3$ sufficiently small, so that $C^+(\M_0^2, \delta_3)$ does not contain all the level 3 propellers. As in the construction of $\mathcal{N}_2$, the meaning of “sufficiently small” for $\delta_3$ will be made precise after the preliminary constructions.

The double propellers at level 3 are given by the collection

\begin{equation}
\tau(P'_{\Gamma(i_1, \ell_1; i_2; \ell_2)}) \quad \text{and} \quad \tau(P'_{\Lambda(i_1, i_2; \ell_1; \ell_2)}) \quad \text{for } \ell_1, \ell_2 \geq b \text{ and } i_1, i_2 = 1, 2.
\end{equation}

Denote the corresponding filled double propellers by $D(1; i_1, \ell_1; i_2, \ell_2)$ and $D(2; i_1, \ell_1; i_2, \ell_2)$, respectively. Observe that the lengths of the double propellers $P'_{\Gamma(i_1, \ell_1; i_2; \ell_2)}$ and $P'_{\Lambda(i_1, i_2; \ell_1; \ell_2)}$ are not bounded above as $\ell_1, \ell_2 \to \infty$. Then set:

\begin{equation}
\mathcal{N}_3 = C^+(\M_0^2, \delta_3) \cup \left\{ \{D(i_0; i_1, \ell_1; i_2, \ell_2) \mid i_0, i_1, i_2 = 1, 2 \text{ and } \ell_1, \ell_2 \geq b \} \right\} \subset K.
\end{equation}
As in the previous analysis of the homotopy types of $\mathfrak{M}_1$ and $\mathfrak{M}_2$, the filled double propellers in \(207\) have both intersections and self-intersections, so their addition to the space $C^+_{3}(\mathfrak{M}_0, \delta_3)$ in \(208\) adds multiple types of exceptional cycles to the homotopy type of $\mathfrak{M}_3$.

Also, as in the analysis of the homotopy type of $\mathfrak{M}_3$, the space $\mathfrak{M}_3$ has families of handles representing cycles of type (2). That is, there are constants $t(i_0; i_1, \ell_1; i_2)$ such that the filled double propellers $D(i_0; i_1, \ell_1; i_2, \ell)$ with $\ell \geq t(i_0; i_1, \ell_1; i_2)$ sufficiently large are not homotopically trivial. Also, there are constants \(209\)

$$\ell(\delta_3; i_0; i_1, \ell_1; i_2) > s(\delta_3; i_0; i_1, \ell_1; i_2) \geq b$$

such that:

1. For $b \leq \ell < s(\delta_3; i_0; i_1, \ell_1; i_2)$, the filled double propellers $D(i_0; i_1, \ell_1; i_2, \ell)$ intersect $C^+_{3}(\mathfrak{M}_0, \delta_3)$ only near their generating curve.
2. For $s(\delta_3; i_0; i_1, \ell_1; i_2) \leq \ell < \ell(\delta_3; i_0; i_1, \ell_1; i_2)$, the filled double propeller $D(i_0; i_1, \ell_1; i_2, \ell)$ is such that its base and tip are contained in $C^+_{3}(\mathfrak{M}_0, \delta_3)$ and do not retract to $\mathfrak{M}_3$ from $C^+_{3}(\mathfrak{M}_0, \delta_3)$. Thus each of these propellers adds a handle of type (2) to $C^+_{3}(\mathfrak{M}_0, \delta_3)$.
3. For $\ell \geq \ell(\delta_3; i_0; i_1, \ell_1; i_2)$, the attachment of the filled double propellers $D(i_0; i_1, \ell_1; i_2, \ell)$ does not change the homotopy type of $C^+_{3}(\mathfrak{M}_0, \delta_3)$.

Again, if the condition $s(\delta_3; i_0; i_1, \ell_1; i_2) < \ell(\delta_3; i_0; i_1, \ell_1; i_2)$ in case (2) is satisfied, then the inclusion $\mathfrak{M}_3 \subset \mathfrak{M}_2$ is not a homotopy equivalence. As before, there is a choice of $0 < \delta_3 < \delta_2/2$ sufficiently small so that this condition is satisfied. The analogs of Lemmas \(23.18\) \(23.19\) and \(23.20\) hold for $\mathfrak{M}_3$.

In general, for $k > 3$, we consider $\delta_k < \delta_{k-1}/2$ such that $C^+_{3}(\mathfrak{M}_0^{k-1}, \delta_k) = C^+_{3}(\mathfrak{M}_0^{k-1}, \delta_k) \cap \mathfrak{M}_{k-1}$ does not contain all of the propellers at level $k$, such that the sequence $\delta_k$ tends to zero sufficiently fast as $k \to \infty$, so that at each stage of the construction there are an increasing number of handles of type (2) attached.

The space $\mathfrak{M}_k$ is defined by attaching to $C^+_{3}(\mathfrak{M}_0^{k-1}, \delta_k)$ the collection of filled propellers at level $k$. As the number of handles in $\mathfrak{M}_{k-1}$ depends on $\delta_{k-1}$, the sets $\mathfrak{M}_{k-1}$ and $C^+_{3}(\mathfrak{M}_0^{k-1}, \delta_k)$ are not homotopy equivalent for $\delta_k$ small enough. Analogous versions of Lemmas \(23.18\) \(23.19\) and \(23.20\) hold for $\mathfrak{M}_k$.

As the constants $\delta_k$ are monotonically decreasing to 0, we have $\mathfrak{M}_{k+1} \subset \mathfrak{M}_k$, and given $\epsilon > 0$, there exists $k > 0$ such that $\mathfrak{M}_k \subset U(\mathfrak{M}, \epsilon)$.

The construction of the spaces $\mathfrak{M}_k$ and their properties as given above yields the following result.

**Proposition 23.21.** Let $\{\mathfrak{M}_k \mid k \geq 0\}$ be the spaces constructed as above. Then there exists a decreasing sequence $\epsilon_k \to 0$ such that for the open sets $U_k = U(\mathfrak{M}_k, \epsilon_k)$ we have:

1. $\mathfrak{M} \subset U_k$ for all $k \geq 0$;
2. the inclusion $\mathfrak{M}_k \subset U_k$ is a pointed homotopy equivalence;
3. for all $k > 0$, there is an inclusion $U_k \subset U_{k-1}$;
4. for all $\epsilon > 0$, there exists $k$ such that $U_k \subset U(\mathfrak{M}, \epsilon)$.

Thus, the collection of inclusions $\mathfrak{U} = \{U_k \subset U_{k-1} \mid k > 0\}$ is a shape approximation for $\mathfrak{M}$.

**Proof.** Lemma \(23.18\) and its extensions to $k > 1$ yield (1). By Lemma \(23.19\) and its extensions to $k > 1$, we can recursively choose $0 < \epsilon_k < \epsilon_{k-1}$ so that the inclusion $\mathfrak{M}_k \subset U(\mathfrak{M}_k, \epsilon_k)$ is a pointed homotopy equivalence, and $U(\mathfrak{M}_k, \epsilon_k) \subset U(\mathfrak{M}_{k-1}, \epsilon_{k-1})$. This yields (2) and (3). Finally, by construction we have $\mathfrak{M} = \cap_{k \geq 0} \mathfrak{M}_k$ and $\epsilon_k \to 0$, which implies (4). \qed

The proof of Theorem \(23.4\) that the minimal set $\Sigma$ of a generic Kuperberg flow does not have stable shape, now follows. The construction of the sets $\mathfrak{M}_k$ shows that the ranks of the groups $H_1(U_k; \mathbb{Z}) \cong H_1(\mathfrak{M}_k; \mathbb{Z})$ tend to infinity as $k \to \infty$. Thus, $\mathfrak{M}$ cannot have stable shape.
To prove Theorem 23.10, it is enough to find a family of loops $\sigma_k \in \mathcal{N}_k$ for every $k$, such that given $\ell \geq 2$ and $p > \ell$, then for any $q > p$ the loop $\sigma_p$ cannot be homotoped inside $\mathcal{N}_\ell$ to a loop in $\mathcal{N}_q$ based at the point $\omega_0$. As loops $\sigma_k$ we take a type (2) loop at level 2 passing twice through the first insertion.

**Lemma 23.22.** For every $k \geq 2$ there exists positive numbers $n_k$ and $m_k$ such that

$$\sigma_k = [a]^{m_k} \cdot [b_1] \cdot [a]^{n_k} \cdot [b_1]$$

is in $\pi_1(\mathcal{N}_k, \omega_0)$ and that for any $n < n_k$ and any suitable $m > 0$ the loop

$$[a]^m \cdot [b_1] \cdot [a]^n \cdot [b_1],$$

is not in $\pi_1(\mathcal{N}_k, \omega_0)$.

**Proof.** In $\mathcal{N}_0$, a loop as in the statement of the lemma, goes from $\omega_0$ to the point $\psi^{m_k} \circ \phi_1 \circ \psi^{n_k} \circ \phi_1(\omega_0)$ that is a level 2 point, and then jumps back to the Reeb cylinder to reach $\omega_0$. Hence, such a loop is in $\mathcal{N}_k$ if the jump can be made inside $C_{m_k}^k(2\mathcal{N}_0^{-1}, \delta_k)$.

Observe first that $\psi^{m_k} \circ \phi_1(\omega_0)$ is a level 1 point of $\tau(P_\gamma)$. As $n$ grows, the level 2 propellers $\tau(P_{\gamma(n)}\downarrow)$ get longer. This is due to the fact that the basepoints $p(t; 1, n)$ of the curves $\gamma(t; 1, n)$ tend to the special points in $L^\gamma$. Hence, for $n_k$ big enough, it is possible to go from the tip of the propeller $P_{\gamma(n_k)}$ down to a level 1 point $q_1 \in \mathcal{N}_1$ inside $\mathcal{N}_k$. Observe that the tip of the propeller is a point of the form

$$\psi^{m_k} \circ \phi_1 \circ \psi^{n_k} \circ \phi_1(\omega_0),$$

for some $m'_k > 0$. Assume without loss of generality that $q_1 \in T_\delta$.

If it is possible to join $q_1$ to a point in the Reeb cylinder by a jump, that is a path in $\mathcal{N}_k$ transversal to $\mathcal{N}_0$, then the point in the Reeb cylinder is $\omega_0$, by construction. In this case, set $m_k = m_k$ and $m_k' = 0$. If not, there is a $m_k'' > 0$ such that it is possible to join $\psi^{m_k''}(q_1)$ to $\omega_0$ by a jump inside $\mathcal{N}_k$. Set $m_k = m_k' + m_k''$. Choose $n_k$ to be the minimal value such that the tip of $P_{\gamma(n_k)}$ can be joined to a point $q_1$ inside $\mathcal{N}_k$. Construct $\sigma_k$ by concatenating the paths:

1. From $\omega_0$ to $\psi^{m_k'} \circ \phi_1 \circ \psi^{n_k} \circ \phi_1(\omega_0)$ along the edges of $T_\delta$;
2. From $\psi^{m_k'} \circ \phi_1 \circ \psi^{n_k} \circ \phi_1(\omega_0)$ to $q_1$ by a jump in $\mathcal{N}_k$;
3. From $q_1$ to $\psi^{m_k''}(q_1)$ along the edges of $T_\delta$;
4. From $\psi^{m_k''}(q_1)$ to $\omega_0$ by a jump in $\mathcal{N}_k$.

Observe that the image of $\sigma_k$ in $\pi_1(\mathcal{N}_0, \omega_0)$ is a loop of the form

$$[a]^{m_k} \cdot [b_1] \cdot [a]^{n_k} \cdot [b_1]$$

Clearly, for any $n < n_k$ and any suitable $m > 0$ the loop

$$[a]^m \cdot [b_1] \cdot [a]^n \cdot [b_1],$$

is not in $\pi_1(\mathcal{N}_k, \omega_0)$. □

To prove Theorem 23.10 take $\ell \geq 2$ and $p \geq \ell$. We prove next that for a sequence $\delta_k$ decreasing sufficiently fast, the loop $\sigma_p$ is not in the image of the inclusion map $\pi_1(\mathcal{N}_q, \omega_0) \to \pi_1(\mathcal{N}_\ell, \omega_0)$ for any $q > p$.

By the choice of $n_p$, there exists $\delta < \delta_p$ for which it is impossible to join the point $\psi^{m_p} \circ \phi_1 \circ \psi^{n_p} \circ \phi_1(\omega_0)$ to a level 1 point by a jump in $C_{m_k}^k(2\mathcal{N}_0^{-1}, \delta)$. Assume that $\delta_{p+1} \leq \delta < \delta_p$.

Consider a loop $\sigma_p$ and suppose that it is in the image of the inclusion map $\pi_1(\mathcal{N}_q, \omega_0) \to \pi_1(\mathcal{N}_\ell, \omega_0)$ for some $q > p$. Then there is a loop $\tilde{\sigma} \in \mathcal{N}_q$ such that $\tau_\ell(\tilde{\sigma}) = [a]^{m_p} \cdot [b_1] \cdot [a]^{n_p} \cdot [b_1]$, in $\pi_1(\mathcal{N}_q, \omega_0)$. This is a contradiction, since $\delta_q \leq \delta_{p+1} < \delta < \delta_p$ and hence it is impossible to join by a jump any point of the level 2 propeller $\tau(P_{\gamma(1,n_p)})$. This proves Theorem 23.10.
We can now forget about the base point \( \omega_0 \), in which case the Mittag-Leffler condition becomes more subtle. As a warm-up for the proof of Theorem 23.9, let us understand how to move the loops \( \sigma_k \) considered as homology classes, so that the level along the new loop is bounded below by a given \( \ell \geq 1 \). In other words, the homology class loop \( \sigma_k \subset \mathfrak{H}_k \) in \( H_1(\mathfrak{H}_k; \mathbb{Z}) \) can be represented by a loop \( \bar{\sigma}_k \) along wich the level is lower bounded by any \( \ell \geq 1 \).

To simplify the notation, assume that \( m_k = m'_k \) and \( m''_k = 0 \). The loop \( \sigma_k \) can be seen as the concatenation of the path in \( T_\Phi \) from \( \omega_0 \) to \( \overline{\psi}^{m_k} \circ \overline{\phi}_1 \circ \overline{\psi}^{m''_k} \circ \overline{\phi}_1(\omega_0) \) followed by a segment in the rectangle \( R_0 \) back to \( \omega_0 \). The loop \( \bar{\sigma}_k \) will be based at some point \( \xi \in T_\Phi \cap R_0 \) and composed by a path in \( T_\Phi \) from \( \xi \) to \( \overline{\psi}^{m_k} \circ \overline{\phi}_1 \circ \overline{\psi}^{m''_k} \circ \overline{\phi}_1(\xi) \) followed by a short segment in \( R_0 \) back to \( \xi \). For such a loop, saying that the level is bounded below by \( \ell \) means that \( n_0(\xi) \geq \ell \).

Consider \( \overline{\psi}^{m_k} \circ \overline{\phi}_1 \circ \overline{\psi}^{m''_k} \circ \overline{\phi}_1 \in \mathcal{G}_R \) and the associated word in \( \mathcal{G}_K \), that is the element \( \psi^{m_k} \circ \phi_1^+ \circ \psi^{m''_k} \circ \phi_1^+ \). The domain of this element is an open neighborhood of \( \omega_1 \). For simplicity, assume further that the jumps take place in the rectangle \( \mathcal{R}_0 \cap \mathcal{R}_0 \), since \( \overline{\psi}^{m_k} \circ \overline{\phi}_1 \circ \overline{\psi}^{m''_k} \circ \overline{\phi}_1(\omega_0) \) is contained in an \( \delta_k \)-neighborhood of the path in \( T_\Phi \) from \( \omega_0 \) to \( \overline{\psi}^{m_k} \circ \overline{\phi}_1 \circ \overline{\psi}^{m''_k} \circ \overline{\phi}_1(\omega_0) \).

Recall that \( \mathcal{R}_0 \) is composed by the union of \( C^\ell_k(\mathcal{R}_0^{k-1}, \delta_k) \) and the filled propellers at level \( k \). Take a loop \( L \subset \mathfrak{N}_k \), since \( \mathcal{N}_k \) contains a \( \delta_k \)-one sided neighborhood of \( \tau(\mathcal{R}') \), we can find move \( L \) slightly and locally, so that it is disjoint from the Reeb cylinder \( \tau(\mathcal{R}') \). Further, we can assume that \( L \) is composed by paths along the edges of \( T_\Phi \) and parts that are transverse to \( \mathcal{R}_0 \), or jumps. Thus \( L \) can be described as the concatenation of paths \( L_i \subset T_\Phi \) and jumps \( J_i \), where each \( L_i \) is followed by \( J_i \) and \( 1 \leq i \leq n \). Hence from \( L_n \) follows the jump \( J_n \) back to \( L_1 \). We denote the disjoint union of the tangent paths \( T_\Phi(L) \).

For simplicity, assume further that the jumps take place in the rectangle \( \mathcal{R}_0 \) and that \( L \) is oriented. These assumptions will simplify the explanations in what follows. We can associate to each tangent path \( L_i \) an element \( \varphi_i \in \mathcal{G}_R^* \) mapping the initial point of \( L_i \) to its endpoint. Recall that \( T_\Phi \) is a tree plus a loop, but
since $L$ is disjoint of the Reeb cylinder, $T_\phi(L)$ does not contains the loop of $T_\phi$. Thus each path $L_i$ can be homotoped to a path along which the level is monotone. Hence the elements $\varphi_i$ are such that either $\varphi_i$ or $\varphi_i^{-1}$ is represented by a monotone (increasing) word as in Definition 21.5.

**Lemma 23.23.** Let $L \subset \mathcal{N}_k$ be a loop in standard form and $p_0 \in T_\phi(L)$ such that $n_0(p_0) \leq n_0(p)$ for any $p \in T_\phi(L)$. Then for any $\ell \geq n_0(p_0) + 1$ there exists a loop $\tilde{L} \in \mathcal{N}_k$ that is homologous in $\mathcal{N}_{k-1}$ to $L$ and such that $n_0(p) \geq \ell$ for any $p \in T_\phi(L)$.

**Proof.** Assume without loss of generality, that $p_0 \in R_0$ is the starting point of a tangent path. This is always possible since the level along a tangent path is monotone increasing or decreasing, thus $p_0$ can be taken to be an endpoint of a tangent path $L_1$ and modulo changing the orientation of $L$ we can assume that $p_0$ is the starting point of $L_1$. We denote $p_1$ the other endpoint of $L_1$, then $p_1 = \varphi_1(p_0)$ and from $p_1$ follows a jump to a point $p'_1$.

Let $n$ be the number of tangent paths in $L$. We apply the above notation to all the loop $L$, that is a tangent path $L_i$ starts at the point $p'_{i-1}$ and ends at the point $p_i$, with $\varphi_i(p'_{i-1}) = p_i$. Then follows a jump from $p_i$ to $p'_i$. Set the last jump from $p_n$ to $p'_0 = p_0$.

Consider $\varphi_1$ and its lift $\widetilde{\varphi}_1$ to $\hat{G}_1$. By hypothesis the point $p_0$ is a point in the transversal $T$ that belongs to a simple curve in $\mathcal{M}_0 \cap R_0$. By definition $p'_0(p_0)$ is the lower endpoint of the corresponding curve if $j = 1$ and the upper endpoint if $j = 2$, and by construction it is in the domain of $\widetilde{\varphi}_1$, where the value of $j$ is determined by $\varphi_1$.

For any $\ell > n_0(p_0)$ there exists a level $\ell$ point $\xi \in T \cap R_0$ such that $\varphi_i(p'_0(\xi)) \in \text{Dom}(\widetilde{\varphi}_1)$, for $j = 1$ or $j = 2$ depending on $\varphi_1$. Moreover, $\xi$ can be taken arbitrarily close to $p_0$. Take $t_{p_0} > 0$ and $k_{p_0} > 0$ such that

$$
\Phi_{t_{p_0}}(p'_0(p_0)) = \widetilde{\varphi}_1(p'_0(p_0)) = \hat{\Phi}_{k_{p_0}}(p'_0(p_0)),
$$

and $t_{t_0} > 0$ and $k_{t_0} > 0$ such that

$$
\Phi_{t_{t_0}}(p'_0(\xi)) = \widetilde{\varphi}_1(p'_0(\xi)) = \hat{\Phi}_{k_{t_0}}(p'_0(\xi)).
$$

Then for every $t'_0 > 0$ there exists $\epsilon > 0$ such that if $d_{\mathcal{R}_0}(p_0, \xi) < \epsilon$ then for every $0 \leq s \leq t_{p_0}$ there exists $0 \leq s' \leq t_{t_0}$ such that

$$
d_{k_{t_0}}(\Phi_s(p'_0(p_0)), \Phi_{s'}(p'_0(\xi))) < \epsilon'.
$$

Then for every $0 \leq k \leq k_{p_0}$ there exists $0 \leq k' \leq k_{t_0}$ such that

$$
d_{\mathcal{R}_0}(\pi_{\mathcal{M}_0}(\hat{\Phi}_k(p'_0(p_0))), \pi_{\mathcal{M}_0}(\hat{\Phi}_{k'}(p'_0(\xi)))) < \epsilon'.
$$

Hence, we can choose $\xi$ so that the $\delta_{k_0}$-neighborhood of the path $L_1$ contains the path in $T_\phi$ from $\xi$ to $\varphi_1(\xi)$. In other words, these two paths are homologous in $\mathcal{N}_{k-1}$.

Observe that $r(\xi) > r(p_0)$, by the nesting property of ellipses. Since the level is monotone up along $L_1$, the point $\xi_1 = \varphi_1(\xi) \in T$ is closer to $p_1$ than $\xi$ to $p_0$, that is

$$
d_{\mathcal{R}_0}(\xi_1, p_1) < d_{\mathcal{R}_0}(\xi, p_0).
$$

Hence for $\xi$ close enough to $p_0$, it is possible to jump from $\xi_1$ to $p'_1$ and from $p_n$ to $\xi$ inside $\mathcal{N}_{k-1}$.

Let $\tilde{L}_1$ be the loop obtained from $L$ by changing the sequence $p_n \to p_0 \to p_1 \to p'_1$ in $L$, for the sequence $p_n \to \xi \to \xi_1 \to p'_1$, that is by construction homologous to $L$ in $\mathcal{N}_{k-1}$. Observe that the level along the tangent path between $\xi$ and $\xi_1$ is bounded below by $\ell$.

If for any $p \in T_\phi(L_1)$ we have $n_0(p) \geq \ell$ set $\tilde{L}_1 = L$. If not, start the substitution process again on $\tilde{L}_1$. That is choose a point $p_{0,1} \in T_\phi(L_1)$ minimizing the level among points in $T_\phi(L_1)$, and then orient $\tilde{L}_1$ so that $p_{0,1}$ is the starting point of one of the tangent paths in $\tilde{L}_1$. By replacing as above the tangent path starting at $p_{0,1}$ we obtain a new loop $\tilde{L}_2 \in \mathcal{N}_{k-1}$ homologous to $\tilde{L}_1$. 
If the level along $\tilde{L}_2$ is bounded below by $\ell$ set $\tilde{L}_2 = \tilde{L}$. If not we apply the process again. After applying the process at most $n$ times, we obtain a loop $\tilde{L}$ along which the level is bounded below by $\ell$ that is homologous to $L$ in $\mathfrak{N}_{k-1}$.

To prove Theorem 23.9 consider $\ell \geq 2$. We start taking $p > \ell$ as in the following lemma.

**Lemma 23.24.** Let $D_1$ and $D_2$ be two filled propellers at level $\ell$. Consider $D_1, D_1 \in \mathcal{W}$ such that $\tau(D_1) = D_1$ for $i = 1, 2$. Let $\eta_i \in D_i \cap R_0$ so that

$$d_{R_0}(\eta_1, \eta_2) = \min\{d_{R_0}(\xi_1, \xi_2) | \xi_i \in D_i \cap R_0\}.$$

Then there exists $p > \ell$ such that if $d_{R_0}(\eta_1, \eta_2) < \delta_p$ then $D_i$ retracts to $C^{+}_{\mathfrak{N}}(\mathfrak{M}_{0}^{\ell} - 1, \delta_\ell)$ for $i = 1$ and 2.

**Proof.** By Lemma 23.20 and its higher level analogs, there is a finite number of filled double propellers at level $\ell$ that attaching them to $C^{+}_{\mathfrak{N}}(\mathfrak{M}_{0}^{\ell} - 1, \delta_\ell)$ generate new handles, the type (2) level $\ell$ filled double propellers. Let $B_1, B_2, \ldots, B_k$ be the filled double propellers in $\mathcal{W}$ so that $\tau(B_i)$ is one of the filled double propellers at level $\ell$ adding a handle. Take $p > \ell$ big enough, so that $\delta_p$ is smaller than the distance between any point in $B_i$ and any point in $B_j$, for $i \neq j$ and $1 \leq i, j \leq k$. The conclusion of the lemma holds for such a choice of $p$. □

For $p > \ell$ as in Lemma 23.24 take a loop $L_p \in \mathfrak{N}_p$ and its image in $\mathfrak{N}_\ell$. We assume that the image is non-trivial. We need to prove that there exists a loop $\tilde{L}_p$ in the image of the map $H_1(\mathfrak{N}_q; \mathbb{Z}) \rightarrow H_1(\mathfrak{N}_\ell; \mathbb{Z})$ homologous to $L_p$ in $\mathfrak{N}_\ell$, for any $q > p$.

By Lemma 23.23 there exists a loop $L'_p$ homologous to $L_p$ in $\mathfrak{N}_{p-1} \subset \mathfrak{N}_\ell$ such that $n_0(p) \geq \ell$ for any $p \in T_\Phi(L'_p)$. Then $L'_p$ is contained in the union of the filled propellers at level $\ell$.

Fix an orientation of $L'_p$. Take a filled propeller at level $\ell$

$$D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell),$$

whose intersection with $L'_p$ is non-trivial and let $L_{p,1}$ be the path in the intersection. Recall that the set $D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \subset \mathcal{W}$, such that $\tau(D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)) = D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)$, is diffeomorphic to a ball and it contains propellers at any level greater than $\ell$. Assume without loss of generality that the endpoints of $L_{p,1}$ are in $T_\Phi$.

If $L_{p,1} = L'_p$ then there is homology transformation inside the filled double propeller taking $L'_p$ to a loop $\tilde{L}_p$ contained in $\mathfrak{N}_q$. Since we are performing the transformation inside a filled double propeller of level $\ell$, the loops $L'_p$ and $\tilde{L}_p$ are homologous in $\mathfrak{N}_\ell$ and $L_p$ is the loop we are looking for.

We are left with the case $L_{p,1} \neq L'_p$. Assume that $L_{p,1} \neq L'_p$, and define in an analogous way the part $L_{p,2}$ of $L'_p$, the path that is immediately after $L_{p,1}$. Thus $L_{p,2}$ is contained in a filled propeller at level $\ell$ that we denote by $D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)$. Analogously define $L_{p,i}$ for $1 \leq i \leq n'$ for some $n' \geq 2$.

Inside each propeller at level $\ell$, the paths $L_{p,i}$ can me moved to a homologous path having the same endpoints and contained in $\mathfrak{N}_q$. We now deal with the concatenation of the paths $L_{p,i}$, to simplify the notation we work with the concatenation of $L_{p,1}$ and $L_{p,2}$.

There are two possibilities for the concatenation of $L_{p,1}$ and $L_{p,2}$:

1. The concatenation is along an intersection of the corresponding filled double propellers

$$D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \quad \text{and} \quad D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell).$$

Recall that such an intersection is contained in $E_1 \cup E_2 \cup S_1 \cup S_2$.

2. The concatenation is a jump inside $C^{+}_{\mathfrak{N}}(\mathfrak{M}_{0}^{\ell} - 1, \delta_\ell) \subset C^{+}_{\mathfrak{N}}(\mathfrak{M}_{0}^{\ell} - 1, \delta_\ell)$. 

For case (1), recall that the boundary of $D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)$ is the propeller generated by either the curve $\Gamma(i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \subset L_{i_0}^-$ if $i_0 = 1$ or the curve $\Lambda(i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \subset L_{i_0}^+$ if $i_0 = 2$.

The intersection of $D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)$ and $D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)$ where $L'$ passes is inside a level $\ell + 1$ curve, assume that this curve is $\tau(\Gamma(i_1, \ell_1; \cdots; i_\ell, \ell_\ell; i_{\ell + 1}, \ell_{\ell + 1}))$ for some $i_{\ell + 1} = 1$ and $\ell_{\ell + 1} \geq b$. Thus we are assuming that $i_0 = 1$ (the case $i_0 = 2$ is analogous). Also, since this curve belongs to $D(1; i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \cap E_{\ell+1}$, we are assuming that $\Gamma(i_1, \ell_1; \cdots; i_\ell, \ell_\ell; i_{\ell + 1}, \ell_{\ell + 1})$ is contained in the disc-like region $L^-(i_0'; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)$ and thus $\ell_{\ell + 1} = \ell'_\ell$.

Since $\Gamma_q(\mathcal{M}_{0}^{\ell-1}, \delta_q) \subset \mathcal{N}_q$ and $q > \ell$, the one sided $\delta_q$-neighborhood of $\tau(\Gamma(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell; i_{\ell + 1}, \ell_{\ell + 1}))$ is in $\mathcal{N}_q$. Inside $\mathcal{N}_q$ we can find paths $L_{p,1}$ and $L_{p,2}$ in $\mathcal{N}_q$, that are homologous to $L_{p,1}$ and $L_{p,2}$ respectively, and such that:

- $L_{p,1}$ and $\widehat{L}_{p,1}$ are both contained in $D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)$ and have the same starting point;
- $L_{p,2}$ and $\widehat{L}_{p,2}$ are both contained in $D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)'$ and have the same endpoint;
- the endpoint of $\widehat{L}_{p,1}$ is the starting point of $\widehat{L}_{p,2}$ and belongs to the curve $\tau(\Gamma(i_1, \ell_1; \cdots; i_\ell, \ell_\ell; i_{\ell + 1}, \ell_{\ell + 1}))$.

Hence the concatenation $L_{p,1} \to L_{p,2}$ is homologous in $\mathcal{N}_q$ to the concatenation $\widehat{L}_{p,1} \to \widehat{L}_{p,2}$, and the path $L_{p,1} \to \widehat{L}_{p,2}$ is contained in $\mathcal{N}_q$. Since these two paths have common starting and ending points, the concatenation in case (1) is solved.

We are left with case (2). Let $\xi_i \in L_{p,i}$ for $i = 1, 2$ be the endpoints of the jump between $L_{p,1}$ and $L_{p,2}$, that is by hypothesis a jump contained in $\mathcal{N}_q$. Then $d_{\mathcal{R}_p}(\xi_1, \xi_2) < \delta_p$, and by the hypothesis on $p$, the filled double propellers

$$D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell) \quad \text{and} \quad D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell),$$

retract to $C_{\mathcal{R}_q}(\mathcal{M}_{0}^{\ell-1}, \delta_p)$.

First, $L_{p,1}$ is homologous inside $D(i_0; i_1, \ell_1; \cdots; i_\ell, \ell_\ell)$ to a path $\widehat{L}_{p,1} \subset \mathcal{N}_q$ having the same endpoints. Second, in $\mathcal{N}_q$, since $D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)$ retracts to $C_{\mathcal{R}_q}(\mathcal{M}_{0}^{\ell-1}, \delta_p)$, the path $L_{p,2}$ is homologous to a path in $C_{\mathcal{R}_q}(\mathcal{M}_{0}^{\ell-1}, \delta_p)$ and also to a path $\widehat{L}_{p,2}$ contained in $D(i'_0; i'_1, \ell'_1; \cdots; i'_\ell, \ell'_\ell)$, such that:

- the starting point of $\widehat{L}_{p,2}$ is the endpoint of $\widehat{L}_{p,1}$;
- the endpoint of $\widehat{L}_{p,2}$ can be joined to the endpoint of $L_{p,2}$ by a jump $J_2$ in $\mathcal{N}_q$. By construction, this jump is of length less than $\delta_p$.

Thus replacing $L_{p,1} \to L_{p,2}$ by $\widehat{L}_{p,1} \to \widehat{L}_{p,2} \to J_2$ we obtain a new loop $L''_p$ homologous to $L_p$ in $\mathcal{N}_{q-1} \subset \mathcal{N}_q$ such that $n_0(p) \geq \ell$ for any $p \in T_q(L''_p)$. The path $L_{p,1} \to L_{p,2}$ is replaced by $\widehat{L}_{p,1} \to \widehat{L}_{p,2}$ that is $\mathcal{N}_q$. Moreover, if $L'_{p}$ intersects $k$ filled double propellers of level $\ell$, then $L''_{p}$ intersects $k - 1$ filled double propellers of level $\ell$.

Recursively solving the concatenations of $L_{p,i}$, for $1 \leq i \leq k$, we obtain the desired loop $\widehat{L}_p \in \mathcal{N}_q$, homologous to $L_p$ in $\mathcal{N}_q$. This finishes the proof of Theorem 23.9.

As discussed in the introduction, Theorem 23.9 does not answer the questions of the movability of $\mathcal{M}$.
