polynomial homotopy continuation

A polynomial homotopy is a family of polynomial systems, where the systems in the family depend on one parameter.

For example, the homotopy

$$h(\mathbf{x}, t) = \gamma(1 - t)g(\mathbf{x}) + tf(\mathbf{x}) = \mathbf{0}, \text{ random } \gamma \in \mathbb{C},$$

connects

- the target system $f(\mathbf{x}) = \mathbf{0}$, at t = 1, to the
- the start system $g(\mathbf{x}) = \mathbf{0}$, at t = 0.

Continuation methods apply path tracking algorithms to track solution paths x(t) starting at solutions of $g(\mathbf{x}) = \mathbf{0}$ and ending at the solutions of $f(\mathbf{x}) = \mathbf{0}$.

step size control

Consider homotopies in one single parameter and assume

- no singularity on each path, and
- In o diverging paths,

except perhaps at the end of the path.

Problem: determine the step size of the path tracker.

- Too small: inefficient.
- Too large: jump off the path, possibly onto another path.

the path jumping problem

Curves are far apart, with high curvature:

Curves are close to each other, with low curvature:

alternatives to numerical continuation

Numerical continuation applies an adaptive step size control in a predictor-corrector method with double precision arithmetic.

Alternatives to numerical continuation:

- intervals, parallelotopes, or ball arithmetic [Kearfott and Xing, 1994], [Martin, Goldsztejn, Granvilliers, Jermann, 2013], [Lecerf and van der Hoeven, 2016];
- symbolic deformation methods [Jeronimo, Matera, Solernó, and Waissbein, 2009], [Hauenstein, Safey El Din, Schost, Vu, 2021];
- certified homotopy tracking [Beltrán and Leykin, 2013], [Xu, Burr, and Yap, 2018].

(The above list of references contains just a sample.)

Padé approximants as predictors

detecting nearby singularities

Applying the ratio theorem of Fabry, we can detect singular points based on the coefficients of the Taylor series.

Theorem (the ratio theorem, Fabry 1896)

If for the series $x(t) = c_0 + c_1 t + c_2 t^2 + \dots + c_n t^n + c_{n+1} t^{n+1} + \dots$,

we have $\lim_{n\to\infty} c_n/c_{n+1} = z$, then

• z is a singular point of the series, and

• it lies on the boundary of the circle of convergence of the series. Then the radius of this circle is |z|.

The ratio c_n/c_{n+1} is the pole of Padé approximants of degrees [n/1] (*n* is the degree of the numerator, with linear denominator).

the ratio theorem of Fabry and Padé approximants

Consider
$$n = 3$$
, $x(t) = c_0 + c_1 t + c_2 t^2 + c_3 t^3 + c_4 t^4$.
$$[3/1] = \frac{a_0 + a_1 t + a_2 t^2 + a_3 t^3}{1 + b_1 t}$$

$$(c_0 + c_1t + c_2t^2 + c_3t^3 + c_4t^4)(1 + b_1t) = a_0 + a_1t + a_2t^2 + a_3t^3$$

$$c_0 + c_1t + c_2t^2 + c_3t^3 + c_4t^4$$

$$+ b_1c_0t + b_1c_1t^2 + b_1c_2t^3 + b_1c_3t^4 = a_0 + a_1t + a_2t^2 + a_3t^3$$

We solve for b_1 in the term for t^4 : $c_4 + b_1c_3 = 0 \Rightarrow b_1 = -c_4/c_3$. The denominator of [3/1] is $1 - c_4/c_3t$. The pole of [3/1] is c_3/c_4 .

linearization

Working with truncated power series, computing modulo $O(t^d)$, is doing arithmetic over the field of formal series C[[t]].

Linearization: consider $\mathbb{C}^{n}[[t]]$ instead of $\mathbb{C}[[t]]^{n}$. Instead of a vector of power series, we consider a power series with vectors as coefficients.

Solve $A\mathbf{x} = \mathbf{b}, \mathbf{A} \in \mathbb{C}^{n \times n}[[t]], \mathbf{b}, \mathbf{x} \in \mathbb{C}^{n}[[t]].$

where $A_i \in \mathbb{C}^{n \times n}$ and $\mathbf{b}_i, \mathbf{x}_i \in \mathbb{C}^n$.

イロト イポト イラト イラト

block linear algebra

Computing the first *d* terms of the solution of Ax = b:

$$\begin{array}{l} \left(A_{0}t^{a} + A_{1}t^{a+1} + A_{2}t^{a+2} + \dots + A_{d}t^{a+d} \right) \\ \cdot \left(\mathbf{x}_{0}t^{b-a} + \mathbf{x}_{1}t^{b-a+1} + \mathbf{x}_{2}t^{b-a+2} + \dots + \mathbf{x}_{d}t^{b-a+d} \right) \\ = \mathbf{b}_{0}t^{b} + \mathbf{b}_{1}t^{b+1} + \mathbf{b}_{2}t^{b+2} + \dots + \mathbf{b}_{d}t^{b+d}. \end{array}$$

Written in matrix format:

$$\begin{bmatrix} A_0 & & & \\ A_1 & A_0 & & \\ A_2 & A_1 & A_0 & \\ \vdots & \vdots & \vdots & \ddots & \\ A_d & A_{d-1} & A_{d-2} & \cdots & A_0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_0 \\ \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_d \end{bmatrix} = \begin{bmatrix} \mathbf{b}_0 \\ \mathbf{b}_1 \\ \mathbf{b}_2 \\ \vdots \\ \mathbf{b}_d \end{bmatrix}$$

If A_0 is regular, then solving Ax = b is straightforward.

6 November 2023

イロト イポト イモト イモト

error analysis of a lower triangular block Toeplitz solver Solving $(A_0 + A_1t + A_2t^2 + \dots + A_dt^d)(x_0 + x_1t + x_2t^2 + \dots + x_dt^d)$ $= (b_0 + b_1t + b_2t^2 + \dots + b_dt^d)$

leads to a lower triangular block system:

$$\begin{bmatrix} A_{0} & & & & \\ A_{1} & A_{0} & & & \\ A_{2} & A_{1} & A_{0} & & \\ \vdots & \vdots & \vdots & \ddots & \\ A_{d} & A_{d-1} & A_{d-2} & \cdots & A_{0} \end{bmatrix} \begin{bmatrix} x_{0} \\ x_{1} \\ x_{2} \\ \vdots \\ x_{d} \end{bmatrix} = \begin{bmatrix} b_{0} \\ b_{1} \\ b_{2} \\ \vdots \\ b_{d} \end{bmatrix}$$

Cost to solve: $O(n^3) + O(dn^2)$.

Let κ be the condition number of A_0 . Let $||A_0|| = ||x_0|| = 1$, $||x_d|| \approx \rho^d$. In our context, $\rho \approx 1/R$, where *R* is the convergence radius.

If
$$||A_d|| \approx \rho^d$$
, then $\frac{||\Delta x_d||}{||x_d||} \approx \kappa^{d+1} \epsilon_{\text{mach}}$, and accuracy is lost.

a posteriori and a priori step size control

We solve a polynomial system with a homotopy $h(\mathbf{x}, t) = \mathbf{0}$. An *a posteriori* step size control uses feedback loops.

Extreme choices for α and ϵ (not recommended):

• If $\alpha \leq \epsilon$, then the corrector is not needed.

• If $\alpha = \infty$, then the first feedback loop does never happen. Setting 0.5 for β cuts the step size Δt in half.

An *a priori* step size control does not need feedback loops.

23/48

A D N A B N A B N A

estimating the distance to the nearest path

Consider a Taylor series expansion of the homotopy at one path, truncated after degree 2, to estimate the distance to the nearest path.

The distance $\|\Delta \mathbf{z}\|$ to the nearest path is estimated by

$$\eta = \frac{2\sigma_n(J_h)}{\sqrt{\sigma_{1,1}^2 + \sigma_{2,1}^2 + \dots + \sigma_{n,1}^2}} \lesssim \|\Delta \mathbf{z}\|,$$

where

- $\sigma_n(J_h)$ is the smallest singular value of the Jacobian matrix,
- σ_{i,1} is the largest singular value of the Hessian matrix at the *i*-th polynomial in the homotopy *h*.

With Padé approximants p_i/q_i we compute an estimate for the error e_0 :

$$\left\| x(\Delta t) - \left(\frac{p_1(\Delta t)}{q_1(\Delta t)}, \dots, \frac{p_n(\Delta t)}{q_n(\Delta t)} \right) \right\| \approx \| \boldsymbol{e}_0 \| \, |\Delta t|^k,$$

where k is determined by the degrees of the Padé approximants.

cost analysis

For *n* variables,

- the cost of the linear algebra is $O(n^4)$,
- the cost to differentiate and evaluate *n* Hessians is 2n times the cost of computing the Jacobian,
- for power series truncated at degree n, the cost overhead factor of Newton's method is O(n log(n)).

Relative to a posteriori step size control, the cost overhead of a priori step size control is $O(n \log(n))$.

Use parallel computers to offset the cost overhead.

computational results

Available in PHCpack since v2.4.72, released 1 September 2019. To track a large number of paths, a static workload distribution message passing implementation ran on a 44-core workstation.

Two benchmarks:

- 1,048,576 paths defined by 20 quadrics, one linear equation, the katsura-20 benchmark from computational physics. About 66 solutions have a large condition number of about 10⁷. HOM4PS-2.0para [Li, Tsai, Parallel Computing 2009] reported 4 path jumpings in their runs on katsura-20.
- 1,594,297 paths defined by 13 cubic equations, in noon-13, arising in a model of a neural network.

All runs were done in double precision, no path jumpings occurred.

Homogeneous coordinate formulations are important.

э

28/48

the 184,756 paths to all cyclic 11-roots

The cyclic 11-roots problem is a sparse polynomial system

- in 11 variables with 181,756 isolated solutions;
- the mixed volume of the Newton polytopes equals 181,756. The start system is a system with the same Newton polytopes, but with randomly generated complex coefficients.

A run with phc on some difficult path shows:

- Around t = 0.5, the coordinates take extreme values, suggesting a diverging path.
- But there is no nearby pole at t = 0.5 and phc -u can complete without the bound involving the Jacobian and Hessians.

These computations are confirmed with the program Padé.jl, Julia code written by Simon Telen and Marc Van Barel.

work still in progress ...

Newton polytopes, mixed volumes, and homotopies

- The Newton polytope of a polynomial is the convex hull of the exponents of those monomials appearing with nonzero coefficient.
- A regular subdivision Δ of the polytopes defines homotopies, starting at solutions of systems supported on the faces of Δ.

Theorem (Bernshtein's theorems, 1975)

Let P be the Newton polytopes of $\mathbf{f}(\mathbf{x}) = \mathbf{0}$. Let $\mathbb{C}^* = \mathbb{C} \setminus \{\mathbf{0}\}$. An initial form system of $\mathbf{f}(\mathbf{x}) = \mathbf{0}$ has faces of P as Newton polytopes.

- The mixed volume $V(P) \ge \#$ isolated solutions of $f(\mathbf{x}) = \mathbf{0}$.
- If V(P) > #isolated solutions of f(x) = 0 in C^{*n}, then f(x) = 0 has initial form systems with solutions in C^{*n}.
 - *V*(*P*) is a generically sharp upper bound. For systems with fewer solutions, faces of Newton polytopes certify diverging paths.

the location problem

At the end of a solution path, we may have a singular solution.

At a singular point, the matrix of all partial derivatives is not full rank.

The *location problem* asks to detect the value of the parameter in the homotopy where a singular point occurs.

How many terms in the Taylor series are needed to solve the location problem?

Taylor series of roots of a polynomial homotopy

Consider the monomial homotopy

$$h(x,t) = x^2 - 1 + t = 0,$$

where x is the variable and t the parameter.

• At
$$t = 0$$
, the solutions are $x = \pm 1$.

• At
$$t = 1$$
, we have the double root $x = 0$.

In this test problem, starting at t = 0, we compute 1 as the nearest singularity. paths defined by $h(x, t) = x^2 - 1 + t = 0$

æ

convergence of the coefficient ratios

Proposition (convergence of the coefficient ratios, CASC 2022)

Assume x(t) is a series which satisfies the conditions of the ratio theorem of Fabry, with a radius of convergence equal to one. Let c_n be the coefficient of t^n in the series, then

$$1-\frac{c_n}{c_{n+1}}\Big|$$
 is $O(1/n)$

for sufficiently large n.

The good and the bad:

- + It confirms extensive computational experiments: using 8 terms of series are sufficient to avoid a singularity in the step size control.
- The O(1/n) grows very slowly, e.g. $1/64 \approx 0.016$, $1/256 \approx 0.004$.

one extra bit of accuracy after each doubling of n

э

going past versus going towards a singularity

• Going past a singularity (the red dot):

• Going towards a singularity (the red dot):

recentering and scaling the radius of convergence

At the critical distance to the last pole *P*:

At the right, after recentering the series at t = 0 and scaling, the distance to the closest singularity equals 1, as in the monomial homotopies case studies.

Definition (the last pole)

Given a solution path $\mathbf{x}(t)$ of a homotopy $h(\mathbf{x}, t) = \mathbf{0}$, the last pole *P* is a value for *t* such that

- **(1)** the matrix of all partial derivatives of $h(\mathbf{x}(P), P)$ is rank deficient,
- **2** of all poles, re(P) is closest to the left of 1.

Avoiding and Computing Singularities

Introduction

- polynomial homotopy continuation
- the ratio theorem of Fabry and Padé approximants
- analytic continuation and extrapolation methods

2 A Priori Step Size Control

- linearization to compute Taylor series
- the Fabry-Hesse-Newton-Padé predictor
- cost analysis and computational results

Extrapolating Towards Singular Solutions

- Iogarithmic convergence
- Richardson extrapolation on two illustrative examples
- the Rho algorithm and going past the last pole

4 D K 4 B K 4 B K 4 B K

an example of Ojika, 1987

$$\mathbf{f}(x,y) = \begin{cases} x^2 + y - 3 &= 0\\ x + 0.125y^2 - 1.5 &= 0 \end{cases}$$

has a triple root at (1, 2). Using a total degree start system with random γ , the t_0 after t_* was found at $t_0 = 0.956$.

After reconditioning, with order n = 64, the location is estimated at

1.0265192231142901 + 2.9197227799819557E - 05I

and improved with Richardson extrapolation to

0.9999729580138075 + 8.484367218447337E-06*I*,

which locates the singularity with an error of 10^{-6} .

Done with sympy 1.4, mpmath 1.1.0, and phcpy 1.1.1 (CASC 2022).

-

イロト イヨト イヨト イヨト

one fourfold cyclic 9-root

The cyclic 9-roots problem (solved by Faugère in 2001) has several isolated roots of multiplicity four.

With the plain blackbox solver of PHCpack, one path was selected that ended at one of the fourfold roots. The t_0 after t_* , the location of the last pole, is $t_0 = 0.99832$. After reconditioning, with n = 32, the convergence radius is

 $1.0000000099639 + 4.319265 \text{E}\!-\!09\,\text{I}$

and confirmed in double double precision.

Because of the close proximity to the singularity, no extrapolation is necessary in this case.

- logarithmic convergence
- Richardson extrapolation on two illustrative examples
- the Rho algorithm and going past the last pole

42/48

4 D K 4 B K 4 B K 4 B K

the Rho Algorithm

Let c_n be the *n*th coefficient of the Taylor series of $x(t) = \sqrt{1-t}$. Then $f(n) = \frac{c_n}{c_{n+1}} = \frac{2(n+1)}{2n-1}$.

f(k) converges logarithmically to 1, f(64) has an error of 1.2e-02.

- Richardson extrapolation gives an error of 3.8e-08,
- improved by repeated Aitken to an error of 2.3e-11.

The Rho Algorithm (Wynn, 1955) needs 4 terms for a correct result.

The Rho Algorithm computes even order convergents of Thiele's interpolating continued fraction.

Thiele interpolation recovers f(n) with just 4 points.

3

< 日 > < 同 > < 回 > < 回 > < □ > <

Past the Critical Distance

Just past the critical distance, the last pole *P* is at $-\frac{1}{2} + I$:

More past the critical distance, the last pole *P* is at -1 + 2I:

running the Rho Algorithm

The Rho Algorithm is applied on the sequence c_n/c_{n+1} , k = 0, 1, ..., d,

• c_n is the *n*th coefficient of the Taylor series of x(t), and

•
$$x(t) = \sqrt{a(1-t)(P-t)}$$
, where *a* is such that $x(0) = 1$.

The smallest error of the rho table for various *P* and *d* values:

Р	<i>d</i> = 8	<i>d</i> = 16	<i>d</i> = 32
-1/2 + I	5.0e-01	3.5e-01	1.4e-01
-1/2 + 2I	1.7e-01	9.8e-03	2.6e-05
-1 + 4/	2.5e-02	6.9e-05	6.3e-09
-2 + 8/	3.3e-03	5.3e-07	3.5e-11
-4 +16 <i>l</i>	4.1e-04	4.0e-09	2.4e-12

All calculations happened in double precision.

The coefficients c_n were computed with tolerance 1.0e-12.

イロト イヨト イヨト イヨト

what about past 1?

The Rho Algorithm works well when the last pole *P* is sufficiently far. But what about a pole *Q* with $re(Q) \ge 1$, close to 1?

Example: P = -4 + 16I and Q = 1 - I/2.

The Rho Algorithm applied on the ratios of the coefficients of the series of $x(t) = \sqrt{a(1-t)(P-t)(Q-t)}$ (with *a* such that x(0) = 1) gives error 2.4e-02.

46/48

Conclusions and Extrapolations

The application of the ratio theorem of Fabry, combined with an estimate for the distance to the nearest path, leads to a robust a priori step size control algorithm, capable to track millions of solution paths.

The Rho Algorithm to compute the Fabry ratio works well when applied to problems when there is no other pole near t = 1.

Poles Q with $re(Q) \ge 1$ close to 1 cause problems. Extrapolate then on the roots of the denominator of a [d/2] Padé approximant for increasing values of d, the degree of the numerator.
