NUMERICAL STUDY OF FRACTIONAL NONLINEAR SCHRÖDINGER EQUATIONS

CHRISTIAN KLEIN, CHRISTOF SPARBER, AND PETER MARKOWICH

Abstract. Using a Fourier spectral method, we provide a detailed numerically investigation of dispersive Schrödinger type equations involving a fractional Laplacian. By an appropriate choice of the dispersive exponent, both mass and energy sub- and supercritical regimes can be computed in one spatial dimension, only. This allows us to study the possibility of finite time blow-up versus global existence, the nature of the blow-up, the stability and instability of nonlinear ground states, and the long time dynamics of solutions. The latter is also studied in a semiclassical setting. Moreover, we numerically construct ground state solutions to the fractional nonlinear Schrödinger equation.

1. Introduction

1.1. Background and Motivation. This work is concerned with numerical studies for nonlocal dispersive equations of nonlinear fractional Schrödinger type (fNLS). More specifically, we consider equations of the form

\[ i \partial_t \psi = \frac{1}{2} (-\Delta)^s \psi + \gamma |\psi|^{2p} \psi, \quad \psi(0, x) = \psi_0(x), \]

for \((t, x) \in \mathbb{R} \times \mathbb{R}^d\) and \(p > 0\). In addition, \(\gamma = \pm 1\) distinguishes between focusing (repulsive) \(\gamma = -1\) and defocusing (attractive) \(\gamma = +1\) nonlinearities. Finally, the parameter \(0 < s \leq 1\) describes the fractional dispersive nature of the equation. The fractional Laplacian \((-\Delta)^s\) is thereby defined via

\[ (-\Delta)^s f(x) := \mathcal{F}^{-1}(|k|^{2s} \mathcal{F} f)(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} |k|^{2s} \hat{f}(k) e^{ik \cdot x} \, dk, \]

where \(\hat{f} = \mathcal{F} f\) denotes the Fourier transform of \(f\). Clearly, for \(s = 1\) this is the usual Laplacian, whereas for \(s < 1\) the equation is indeed nonlocal. (The factor \(\frac{1}{2}\) in front of the fractional Laplacian is kept for historic reasons but could be safely scaled away by replacing \(x \mapsto \sqrt{2} x\).)

Equation (1.1) generalizes the classical nonlinear Schrödinger equation (where \(s = 1\)), which is a canonical model for weakly nonlinear wave propagation in dispersive media, cf. eg. [37]. In the context of quantum mechanics the case \(s = \frac{1}{2}\) can be seen as a toy model for the description of particles with a relativistic dispersion relation \(\omega(k) = \sqrt{|k|^2 + m^2}\). This has recently been used in the mathematical description of Boson-stars, see [14, 33]. Fractional NLS also arise in the continuum limit of discrete models with long range interaction [25], in some models of water wave dynamics [20], and by generalizing the Feynman path integral to include also Lévy processes [32].

1
From the mathematical point of view, fNLS equation have recently drawn quite some interest by various authors. For example, the question of local and/or global well-posedness of the initial value problem (1.1) has been studied in [17, 18, 19]. In addition to that, finite-time blow-up of solutions of fNLS (with Hartree type nonlinearities) has been established in [5, 33]. Moreover, the existence, uniqueness and stability properties of the associated standing wave solutions has been investigated in [6, 13, 16]. To this end, we recall that (nontrivial) standing waves are obtained in the case $\gamma = -1$ by setting $\psi(t,x) = \varphi(x)e^{-i\omega t}$, $\omega \in \mathbb{R}$, which leads to the study of the following nonlinear elliptic equation:

\begin{equation}
\frac{1}{2}(-\Delta)^s\varphi - |\varphi|^{2^*_p}\varphi = \omega\varphi,
\end{equation}

see Section 2.2 below for more details.

1.2. Basic mathematical properties of fNLS. In this work, we are mainly interested in the interaction between the (nonlocal) dispersion and the nonlinearity in the time-evolution of (1.1). To this end, we shall take on the point of view that $p > 0$ is fixed and $0 < s \leq 1$ is allowed to vary. Intuitively, we expect the model to be better behaved the stronger the dispersion, i.e. the larger $s > 0$. To obtain more insight, we first note that the following quantities are conserved by the time-evolution of (1.1):

\begin{align}
\text{mass} & \quad M(t) = \int_{\mathbb{R}^d} |\psi(t,x)|^2 \, dx = M(0), \\
\text{energy} & \quad E(t) = \int_{\mathbb{R}^d} \frac{1}{2} |\nabla^s \psi(t,x)|^2 + \frac{\gamma}{p+1} |\psi(t,x)|^{2^*_p+2} \, dx = E(0),
\end{align}

where $\nabla^s \psi = \mathcal{F}^{-1}(|k|^s \hat{\psi})$. Note that in the defocusing case $\gamma = +1$, the energy is the sum of two non-negative terms (the kinetic and nonlinear potential energy).

This, together with the conservation of mass, allows to infer an a-priori bound on the $H^s(\mathbb{R}^d)$ Sobolev norm of $\psi$, as well as its $L^{2^*_p+2}(\mathbb{R}^d)$ norm, provided the embedding $H^s(\mathbb{R}^d) \hookrightarrow L^{2^*_p+2}(\mathbb{R}^d)$ holds. The latter is true for $0 < p < p_*(s,d)$, where

\begin{equation}
p_*(s,d) = \begin{cases} \frac{2s}{d-2s}, & 0 < s < \frac{d}{2}, \\ +\infty, & s \geq \frac{d}{2}. \end{cases}
\end{equation}

In addition to the conservation laws above, the fNLS equation preserves the radial symmetry and is also invariant under the scaling transformation

\begin{equation}
\psi(t,x) \mapsto \psi_{\lambda}(t,x) := \lambda^{s/p} \psi(\lambda^{2s}t, \lambda x),
\end{equation}

for any $\lambda > 0$. In other words, if $\psi$ solves (1.1) then so does $\psi_{\lambda}$. With this in mind, one can check that the under the scaling transformation (1.6), the homogeneous $H^\sigma(\mathbb{R}^d)$ Sobolev norm of $\psi_{\lambda}$ behaves like

\begin{equation}
\|\psi_{\lambda}\|_{H^\sigma} \equiv \|\nabla^s \psi_{\lambda}\|_{L^2} = \lambda^{\frac{d}{2} - \sigma - \frac{s}{p}} \|\psi\|_{H^\sigma}.
\end{equation}

The equation is called $H^\sigma$ critical whenever this scaling leaves the $H^\sigma$ space invariant, i.e. whenever

\begin{equation}
d \cdot \frac{s}{2} - \frac{s}{p} = \sigma.
\end{equation}

For $\sigma = 0$, we therefore obtain the $L^2$ critical, or mass critical case whenever the dispersion rate is $s = s^*(p,d) \equiv \frac{d}{2p}$, or, equivalently, whenever $p = \frac{2d}{s}$. The equation is called mass subcritical if $s > s^*$ and mass supercritical for $s < s^*$ (and vice versa for $p$). This should be compared to the situation for the usual NLS in
which $s = 1$ is fixed. The corresponding mass critical case is found for $p = \frac{4}{d}$,
perticular examples being the cubic NLS in $d = 2$, or the quintic NLS in $d = 1$. It
is well known, cf. [4, 37], that in the mass subcritical case $p < \frac{4}{d}$ the classical NLS
is globally well-posed (regardless of the sign of $\gamma$). On the other hand, finite time
blow-up of solutions in the $H^1(\mathbb{R}^d)$ norm can occur in the focusing case $\gamma = -1$ as
soon as $p \geq \frac{4}{d}$. This means that there exists a finite time $0 < t^* < +\infty$, depending
on the initial data $u_0$, such that
\[
\lim_{t \to t^*} \| \nabla \psi(t, \cdot) \|_{L^2} = +\infty.
\]
Moreover, it is known that for mass critical NLS, the threshold for finite time blow-
up is given by the mass of the corresponding ground state, i.e. the unique positive
radial solution $Q(x) = \varphi(|x|)$ of the nonlinear elliptic equation (1.2), with $\omega = 1$.
In other words, if $p = \frac{4}{d}$ and $\mathcal{M}(u_0) < \mathcal{M}(Q)$, global existence still holds, whereas
blow-up occurs as soon as $\mathcal{M}(u_0) \geq \mathcal{M}(Q)$. For the fractional NLS an analogous
dichotomy appears and has been rigorously studied in, e.g., [17, 33].

As we have seen there is a second conserved quantity, namely the energy. We
therefore can introduce a corresponding second notion of criticality. More precisely,
the energy critical case is obtained for $s = \sigma$, in which case the kinetic energy
of the solution is indeed a scale invariant quantity of the time-evolution. This
yields another critical index $s_\star(p, d) = \frac{d+2}{2(d+1)}$, which is equivalent to $p = p_\star(s, d)$
as defined in (1.5). Clearly, the energy critical index is always smaller than the
mass critical one, i.e. $s_\star < s^\star$. For classical NLS with $s = 1$ fixed, the energy
critical case is given by $p = \frac{4}{d}$ and hence only appears in dimensions $d \geq 3$. The
latter is no longer true for fractional NLS with $s < 1$. In the energy critical and
supercritical case, the quantity $E(t)$ can no longer be used in order to obtain a-priori
estimates on the solution. Furthermore, the classical well-posedness theory for
semilinear dispersive PDEs breaks down as the time of existence of local solutions
in general may depend on the profile $\psi_0$, not only its $H^s$ norm. For classical NLS
($s = 1$), partial results on the existence of solutions in the energy critical case are
still available, see [7, 12, 24, 39], but a complete picture is missing so far. The
corresponding situation for energy critical fNLS has been recently studied in [19].

1.3. Structure of the present work. All of the above considerations paint a
picture in which the theory for fNLS seems to follow closely from the usual NLS
results. While this is certainly true for basic questions such as existence and uniqueness
versus finite time blow-up, the nonlocal nature of (1.1) with $s < 1$ is expected to
have a considerable influence on more qualitative properties of the solution. In
this paper, numerical simulations are performed in order study the influence of a
nonlocal dispersion term on different mathematical questions, including: the par-
ticular type of finite time blow-up (e.g., self-similar or not), qualitative features of the
associated ground states solutions (including their stability), and the possibility
of well-posedness in the energy supercritical regime. The fact that we can vary the
dispersion coefficient $0 < s < 1$, thereby allows us to perform our simulations for
both sub- and supercritical regimes in $d = 1$ spatial dimensions, which is a big
advantage. (In contrast to that, numerical simulations for energy supercritical NLS
require at least $d = 3$, see [8].) For our numerical simulations we will thus fix the
nonlinearity to be cubic, i.e. $p = 1$, in which case (1.1) becomes
\[
\text{fNLS1} \quad \partial_t \psi = \frac{1}{2} (-\Delta)^s \psi + \gamma |\psi|^2 \psi, \quad \psi(0, x) = \psi_0(x), \quad x \in \mathbb{R}.
\]
This equation in $d = 1$ is mass critical for $s^\star = \frac{1}{2}$ and energy critical for $s_\star = \frac{1}{4}$. We
consequently have global well-posedness for $\gamma = +1$ (defocusing case) and $s > \frac{1}{4}$. In
the focusing case $\gamma = -1$, we can expect finite time blow-up of solutions whenever
Finally, the energy supercritical regime corresponds to \( s < \frac{1}{4} \), where, in principle, a different type of blow-up (than in the mass supercritical regime) might happen. The numerical simulations conducted are based on a Fourier spectral methods, to be explained in more detail in the upcoming section. Indeed, the paper is organized as follows:

- In Section 2 we will describe in more detail the numerical methods used to handle the time-evolution, as well as the steady state problem for \( \text{fNLS} \).
- In Section 3 we shall present numerical and analytical methods used for the study the blow-up phenomenon.
- In Section 4 we study numerically the stability of fractional ground states in the mass sub- and supercritical regime.
- In Section 5, we shall study the possibility of finite time blow-up for mass critical and super-critical \( \text{fNLS} \), by comparing the situation with the one occurring for the quintic and septic NLS.
- In Section 6 the time evolution of focusing and defocusing energy (super)critical \( \text{fNLS} \) numerical simulated. The possibility of blow-up is studied and we also study the long time behavior of the scaling invariant \( \dot{H}^s(\mathbb{R}) \) norm in the defocusing case.
- Finally, in Section 7 we study the time-evolution of (1.9) within a semiclassical scaling regime.
- Our main findings are summarized in Section 8.

## 2. Numerical methods

In the following we will discuss the numerical methods used to compute the time-evolution of the solution and its corresponding ground states.

### 2.1. Numerical methods for the time-evolution

For the numerical integration of (1.1), we use a Fourier spectral method in \( x \). The reason for this choice is that the fractional derivatives are most naturally computed in frequency space which is approximated via a discrete Fourier transform computed through an FFT (fast Fourier transform). The excellent approximation properties of a Fourier spectral method for smooth functions are also extremely useful. This is especially important in the context of dispersive equations since spectral methods are known for a minimal introduction of numerical dissipation which (in principle) could overwhelm dispersive effects within our model.

Remark 2.1. For the same reasons, a recent numerical study using the same numerical methods has been conducted for fractional KdV and BBM type equations, see [30].

The discretization in Fourier space leads to a system of (stiff) ordinary differential equations for the Fourier coefficients of \( \psi \) of the form

\[
\partial_t \hat{\psi} = \mathcal{L} \hat{\psi} + \mathcal{N}(\psi),
\]

where \( \mathcal{L} = -|k|^{2s}/2 \) and where \( \mathcal{N}(\psi) = i\gamma |\psi|^2 \bar{\psi} \) denotes the nonlinearity. It is an advantage of Fourier methods that the \( x \)-derivatives and thus the operator \( \mathcal{L} \) are diagonal. For equations of the form (2.1) with diagonal \( \mathcal{L} \), there are many efficient high-order time integrators. In particular, the performance of several fourth order methods was recently compared in [26] by using the (semiclassically scaled) cubic NLS as a bench mark. It was shown that in the defocusing case, a time-splitting scheme as in [1] was the most efficient, whereas in the focusing case a composite Runge-Kutta method [9] is preferable. The two codes are also used to test each other and were found to agree within the indicated numerical precision. We shall therefore use these two approaches also in our case.
In order to test the numerical methods, we take \( \psi_0(x) = Q(x) \), i.e. the ground state solution whose numerical construction is explained in the next subsection. In this case, the time-dependence of the exact solution of (1.1) is simply given by \( \psi(t, x) = Q(x)e^{it} \). A comparison of the numerical solution of the fNLS with initial data \( \psi_0 = Q \) therefore tests both \( Q \) and the time-evolution. In Fig. 1 we take \( p = 1 \) (cubic nonlinearity), \( s = 0.6 \) and show the the difference between numerical solution and \( Q(x)e^{it} \) for \( N = 2^{16} \) and \( N_t = 20000 \) time steps for \( t \leq 6 \). It can be seen that the ground state is reproduced up to errors of order \( 10^{-12} \), i.e., essentially with machine precision (which is roughly \( 10^{-14} \) in our case).

In our numerical computations, we also ensure that the computed relative energy of the solution, i.e.

\[
\Delta E = \left| \frac{E(t) - E(0)}{E(0)} \right| \tag{2.2}
\]

is conserved up to a certain precision \( \Delta E < 10^{-3} \). For the example in Fig. 1, the quantity \( \Delta E \) is of the order of machine precision in accordance with expectations. Generally this quantity is smaller than \( 10^{-10} \) in our computations unless otherwise noted.

### 2.2. Numerical construction of fractional ground states.

Recall that standing wave solutions to (1.1) are obtained in the focusing case \( \gamma = -1 \) by setting \( \psi(t, x) = \varphi(x)e^{-i\omega t} \), \( \omega \in \mathbb{R} \) some frequency. By rescaling

\[
\varphi_\omega = \omega^{1/(2p)} \varphi_1(\sqrt{2}x\omega^{1/(2s)}) \tag{2.3}
\]

we can w.r.o.g. assume \( \omega = 1 \) and hence \( \varphi \equiv \varphi_1 \) solves

\[
\frac{1}{2}(-\Delta)^s \varphi + \varphi = |\varphi|^{2p} \varphi. \tag{2.4}
\]

Solutions \( \varphi \in H^s(\mathbb{R}^d) \cap L^{2p+2}(\mathbb{R}^d) \) to this equation exist for admissible \( 0 < p < p^* \), where \( p_* = p_*(s, d) \) is given by (1.5). Indeed, by invoking Pohozaev-type identities, it can be shown that equation (2.4) does not admit any nontrivial solutions in \( H^s(\mathbb{R}^d) \cap L^{2p+2}(\mathbb{R}^d) \), when \( p \geq p_* \). Of special interest are solutions with minimal energy, so-called ground states, which are known to be real and radially symmetric and thus satisfy

\[
\frac{1}{2}(-\Delta)^s Q + Q = |Q|^{2p+1} \tag{2.5}
\]
For \( s \neq 1 \), ground state solutions \( Q \) decay like \( |x|^{-(d+2s)} \) as \( |x| \to \infty \), i.e., only algebraically fast, see [13]. This is in contrast to the case of the usual NLS ground states obtained for \( s = 1 \), which are known to decay exponentially fast, see, e.g., [4]. Indeed, for \( s = d = 1 \), one has the well-known explicit solution of the so-called bright solitary wave (at time \( t = 0 \)):

\[
Q(x) = \left( \frac{p + 1}{\cosh^2(\sqrt{2}p x)} \right)^{1/(2p)}, \quad 0 < p < p^*.
\]

For fNLS, with \( s < 1 \), no explicit solutions to (2.5) are known.

To numerically solve equation (2.5), we use the same approach as in [30] to which we refer the reader for more details. The basic idea is to expand \( Q \) on a finite interval \( x \in D[\pi, \pi], D > 0 \), in a discrete Fourier series, computed via FFT. In Fourier space, equation (2.5) takes the form

\[
F(Q) := \left( \frac{1}{2} |k|^{2s} + 1 \right) \hat{Q} - \hat{Q}^{2p+1} = 0,
\]

subject to periodic boundary conditions. Due to the slow algebraic decay of \( Q \) for \( s < 1 \), the constant \( D \) thereby has to be chosen sufficiently large in order to reduce the discontinuity of the derivatives of \( Q \) at the boundaries of the computational domain. It is well known that such discontinuities imply an algebraic decrease of the Fourier coefficients with the wave number \( k \) and thus a slow convergence of the numerical approximation with the number \( N \) of Fourier modes. We choose here \( D = 100 \) and \( N = 2^{16} \) Fourier modes. Numerically, \( \hat{Q} \) is approximated by a discrete Fourier transform, i.e., by a finite vector, which implies that a system of \( N \gg 1 \) nonlinear equations has to be solved. To this end, we invoke an iterative Newton method in order to find the (nontrivial) zeroes of the function \( F(Q) \). This means that we iterate

\[
\hat{Q}_{n+1} = \hat{Q}_n - J^{-1}(F)(\hat{Q}_n),
\]

where \( J \) is the Jacobian of \( F \). However, for \( N = 2^{16} \), the dimension of the Jacobian is too high to be efficiently implemented on the used computers, and we therefore apply a Newton-Krylov method. This means that the inverse of the Jacobian is computed via GMRES [35], iteratively. By doing so only the action of the Jacobian on a vector has to be computed, whereas the full Jacobian is never explicitly stored.

An additional obstruction is given by the fact that (2.5), or equivalently (2.7), always has the trivial solution \( \hat{Q} = 0 \). Thus a fixed point iteration in general will converge to the latter. To circumvent this problem, we have to make sure to start sufficiently close to the exact nontrivial solution \( Q \). For \( s = 1 \), the latter is given explicitly by (2.6) and thus, we consequently start with values of \( s \) close to 1, say \( s = 0.9 \), and an initial iterate given by (2.6). Then we use the solution for \( s = 0.9 \) as the starting point for the iteration for \( s = 0.8 \) and so on. The results can be seen in Fig. 2 where we have chosen \( p = 1 \), i.e., a cubic nonlinearity. We see that the smaller \( s < 1 \), the more the ground state solution becomes peaked, and the slower its spatial decay as \( |x| \to \infty \) in accordance with the theoretical predictions.

**Remark 2.2.** The slow decay of \( Q \) also affects the convergence of the iteration, and hence we have to decrease \( s < 1 \) in smaller and smaller increments in order to assure convergence. In each case, the iteration is stopped whenever equation (2.7) is satisfied to better than \( 10^{-12} \). This implies that the solutions are well resolved in Fourier space for larger \( s > 0.5 \). It can be seen in Fig. 3 that the modulus of the Fourier coefficients decreases to machine precision for the high wave numbers, whereas they only decrease to \( 10^{-4} \) for \( s = 0.4 \).
Finally, the total energy and the mass of the ground solutions $Q$ are depicted in dependence of $s$ in Fig. 4. Note that the energy vanishes with numerical precision ($\approx 10^{-5}$) in the $L^2$ critical case, where $p = 1$ and $s = 0.5$.

3. Methods for the numerical study of blow-up

In this section we briefly present the methods used for the numerical study of finite-time blow-up. Firstly we use a dynamic rescaling which allows in principle an adaptive mesh refinement near blow-up. Secondly, we explain how to numerically identify singularities on the real axis by tracing singularities of the solution in the complex plane via the asymptotic behavior of the Fourier coefficients.

3.1. Dynamical rescaling. In the numerical study of blow-up in NLS equations, dynamically rescaled codes have proven to provide an interesting approach, see [37, Chapter 6] and the references therein. In the case of \textit{radially symmetric} solutions...
\[ \psi(t, r) \equiv \psi(t, |x|) \] one thereby introduces the change of variables

\[ (3.1) \quad y = \frac{r}{L(t)}, \quad \frac{d\tau}{dt} = \frac{1}{L^{2s}(t)}, \quad \psi(t, r) = L(t)^{-s/p}\Psi(\tau, y). \]

Using this for the focusing (\( \gamma = -1 \)) fNLS, we find a rescaled equation for \( \Psi \) in the form

\[ (3.2) \quad i\partial_\tau \Psi = ia(\tau) \left( \frac{s}{p} \Psi + y\partial_y \Psi \right) + \frac{1}{2}(-\Delta)^s \Psi - |\Psi|^{2p}\Psi. \]

where \((-\Delta)^s \Psi(x) := \mathcal{F}^{-1}(|k|^{2s} \hat{\Psi}(k))\), for \( k \in \mathbb{R} \), and

\[ (3.3) \quad a = L^{2s-1} \frac{dL}{d\tau} = \frac{d\ln L}{d\tau}. \]

Under this rescaling the mass and energy behave like

\[ (3.4) \quad M = \frac{|s|^{d-1}}{L(\tau)^{d-2s/p}} \int_0^\infty |\Psi(\tau, y)|^2 y^{d-1} dy, \]

and

\[ (3.5) \quad E = \frac{|s|^{d-1}}{L(\tau)^{d-2s-2s/p}} \int_0^\infty \left( \frac{1}{2} |y^{s}\Psi(\tau, y)|^2 - \frac{1}{p+1}|\Psi(\tau, y)|^{2p+2} \right) y^{d-1} dy, \]

where \( y^{s}\partial_y f(x) := \mathcal{F}^{-1}(k^s \hat{f}(k)) \). The scaling function \( L \) should be chosen in such a way that \( L(\tau) \to 0 \), sufficiently fast, as \( \tau \to +\infty \). It is then expected that, as \( \tau \to +\infty \), both \( a \to a^\infty \) and \( \Psi \to \Psi^\infty \) become \( \tau \)-independent (in the mass supercritical case). The profile \( \Psi^\infty \), consequently solves

\[ (3.6) \quad ia^\infty \left( \frac{s}{p} \Psi^\infty + y\partial_y \Psi^\infty \right) + (-\Delta)^s \Psi^\infty - |\Psi|^{2p}\Psi = 0, \quad y \in \mathbb{R}_+. \]

In \( d = 1 \), this is a fractional ordinary differential equation.

**Remark 3.1.** If \( a^\infty = 0 \), this equation corresponds to the standing wave equation (1.2) with \( \omega = 0 \). The associated stationary solution \( \varphi = W(x) \), often called Rubin-Talenti solution, plays a similar role for energy critical NLS, as does the ground state solution \( \varphi = Q(x) \) for mass critical NLS, see [12] for more details.

There are different ways of constructing \( L(t) \), see [37]. One of them invokes the use of an integral norm of \( \psi \) which goes to infinity at the blow-up. This is preferable
from the numerical point of view and hence, we shall choose a scaling which keeps \( \| \partial_y \Psi(\tau, \cdot) \|_{L^2} \) constant. This leads to

\[
L(t)^{d/2+s/p} = \left( \frac{\| \partial_y \Psi_0 \|_{L^2}}{\| \partial_y \Psi(t, \cdot) \|_{L^2}} \right)
\]

where the constant \( \| \partial_y \Psi_0 \|_{L^2} \) is chosen to be \( \| \partial_y \psi_0 \|_{L^2} \). We can read off the time-evolution of \( L \) from (3.7), (3.3) and (3.1), which leads to

\[
a(\tau) = \frac{2|\mathcal{S}^{d-1}|}{(2s/p + 1)\| \partial_y \Psi \|_{L^2}^2} \int_0^\infty |\Psi|^{2p} \Im (\Psi \partial_y^2 \Psi) y^{d-1} dy.
\]

This allows us in principle to study the type of the blow-up for fNLS in a similar way as it has been done for generalized Korteweg-de Vries equations in [27]. But it was shown numerically in [27] that generic rapidly decreasing hump-like initial data lead to a tail of dispersive oscillations towards spatial infinity with slowly decreasing amplitude. Due to the imposed periodicity (in our numerical domain), these oscillations reappear after some time on the opposing side of the computational domain and lead to numerical instabilities in the dynamically rescaled equation.

The source of these problems is the term \( y\Psi_y \) in (3.2) since \( y \) is large at the boundaries of the computational domain. Therefore this term is very sensitive to numerical errors. For gKdV this can be addressed by using high resolution in time and large computational domains. It turns out that for fractional KdV equations, see [30], and for fNLS, the dispersive oscillations have an amplitude that decreases very slowly towards infinity which is also reflected by the slow decrease of the solitons. The consequence of this is that we can not compute long enough with the dynamically rescaled code to get conclusive results. Instead we integrate fNLS directly, as described above, and then we use some post-processing to characterize the type of blow-up via the above rescaling. For instance, we read off the time evolution of the quantity \( L \) from (3.8).

Under the hypothesis that \( L(\tau) \sim \exp(-\kappa \tau) \) with \( \kappa > 0 \) some positive constant, (3.1) yields a connection between \( t \) and \( \tau \). Namely,

\[
L(t) \propto (t^* - t)^{\frac{1}{2}},
\]

where \( t^* > 0 \) is the blow-up time, corresponding to \( \tau = +\infty \). With (3.7) and (3.1), this implies

\[
\| \partial_y \psi(t, \cdot) \|_{L^2}^2 \propto (t^* - t)^{-1/(p+1/(2s))}, \quad \| \psi(t, \cdot) \|_{L^\infty} \propto (t^* - t)^{-1/(2p)}.
\]

In particular, for \( s = 1 \) we have \( L \propto \sqrt{t^* - t} \), which is the expected blow-up rate for NLS in the mass supercritical regime. In the mass critical case \( p = 2 \), one finds a correction to (3.7) in the form

\[
L(t) \propto \sqrt{\frac{t^* - t}{\ln |\ln(t^* - t)|}},
\]

i.e., one has \( \tau \propto \ln(t^* - t)(1 - \ln |\ln(t^* - t)|) \) instead of \( \tau \propto \ln(t^* - t) \). This so-called log-log-scaling regime for mass critical NLS has been rigorously proved in [34]. We will test whether such scalings can be observed in the numerical experiments for fNLS, but it cannot be expected that the logarithmic corrections can be seen here.

3.2. Singularity tracing in the complex plane. In the case of a finite-time blow-up, we observe essentially two types of behavior of the numerical solution. Either the \( L^\infty \) norm of the solution becomes so large that the computation of the nonlinear terms in the fNLS equation leads to an overflow error. In this case the code breaks down by producing NaN results. The other possibility is that the code runs out of resolution in Fourier space which is indicated by a deterioration of the Fourier coefficients. The latter allows for an identification of an appearing
singularity as follows (see also [28, 29, 36]): We recall the fact that, in the complex plane, a (single) singularity \( z_0 \in \mathbb{C} \) of a real function \( f \), such that \( f(z) \sim (z - z_0)^\mu \), with \( \mu \notin \mathbb{Z} \), results in the following asymptotic behavior for the corresponding Fourier transform

\[
\left| \hat{f}(k) \right| \sim \frac{1}{k^{\mu + 1}} e^{-k\delta}, \quad |k| \gg 1,
\]

where \( \delta = \text{Im} \ z_0 \). The quantity \( \mu \) thereby characterizes the type of the singularity.

In [28, 29] this approach was used to quantitatively identify the time where the singularity hits the real axis, i.e., where the real solution becomes singular, since it was shown that the quantity \( \delta \) can be reliably identified from a fitting of the Fourier coefficients. Unfortunately, this is not true for \( \mu \), for which the numerical inaccuracy is too large. In the case of focusing NLS, it was shown in [29] that the best results are obtained when the code is stopped once the singularity is closer to the real axis than the minimal resolved distance via Fourier methods, i.e.,

\[
m := 2\pi D N,
\]

with \( N \in \mathbb{N} \) being the number of Fourier modes and \( 2\pi D \) the length of the computational domain in physical space. All values of \( \delta < m \) cannot be distinguished numerically from 0.

Note that the time at which the code is stopped because of the criterion above is not the same as the blow-up time itself. Rather, it is only the time where the code stops to be reliable. As mentioned above, we will always provide sufficient resolution in time so that that only the lack of resolution in Fourier space makes the code stop. The blow-up time will then be determined from the numerical data by fitting to the scalings given in the previous subsection. We generally choose the time step in blow-up scenarios such that the accuracy is limited by the resolution in Fourier space, i.e., that a further reduction of the time step for a given number of Fourier modes does not change the final result within numerical accuracy.

4. Stability of ground states

In this section we will study perturbations of the ground state solutions constructed before. This is done for cubic nonlinearities \( p = 1 \) and different values of the parameter \( s \). To this end, we will consider initial data for (1.9) of the form

\[
\psi_0(x) = \alpha Q(x), \quad \alpha \in \mathbb{R},
\]

where \( Q \) is the ground state solution determined numerically as described in Section 2.2. The factor \( \alpha \) will be either chosen to be a constant \( \alpha \approx 1 \) or to be an \( x \) dependent phase. Note that qualitatively similar results as shown here are also found for localized perturbations of the form: \( \psi_0(x) = Q(x) + \varepsilon e^{-|x|^2} \), with \( \varepsilon < 1 \).

4.1. Perturbed ground states in the mass subcritical regime. It is known [6] that the ground state solutions are stable in the mass subcritical case, i.e. \( s > \frac{1}{2} \).

In fact, if we propagate initial data of the form (4.1) we find that the perturbed ground state starts to oscillate around what appears to be a stationary solution with frequency \( \omega \in \mathbb{R} \), i.e. we find that \( \psi(t, x) = Q_\omega(x)e^{i\omega t} \). This can be seen in Fig. 5, where we have solved the initial value problem (1.9) subject to data (4.1) with \( \alpha = 0.9 \). We use \( N = 2^{16} \) Fourier modes for \( x \in [100, \pi] \) and \( N_t = 10^4 \) time steps for \( t < 30 \). It can be seen that the initial hump decreases in height and then starts to exhibit damped oscillations around what appears to be a rescaled ground state function. This is reminiscent of the so-called breather solutions known for classical NLS.
The damped oscillations are clearly visible if one looks at the $L^\infty$ norm of the solution, see Fig. 6. It can be seen from there that the $L^\infty$ norm becomes constant as $t \to +\infty$. Since the $L^2$ norm of the solution is a conserved quantity, the scaling (1.6) allows us to infer a bound on $\omega$, given by $\omega^{1-1/(2s)} \leq \alpha^2$. For $\alpha = 0.9$ this would imply that the $L^\infty$ norm of the ground state with the maximal $\omega$ would be roughly equal to 1.146. Fig. 6 suggests that this is indeed the amplitude of the final state. This would mean that the ground state is stable, and that a perturbed ground state leads asymptotically for large $t$ to a steady state with the mass of the perturbed state. In the same figure we show the $L^\infty$ norm of the solution for the fNLS equation for initial data (4.1) with $\alpha = 1.1$. There are much more oscillations in this case, but the final state appears to have an $L^\infty$ norm of roughly 1.8 (the maximal possible $L^\infty$ norm of the ground state having the same mass as the initial data would be $\approx 1.800$). Thus also in this case the final state appears to be a stationary solution corresponding to the mass of the initial data.
For our final numerical test within this section, we first recall that the classical NLS equation \((s = 1)\) is Galilei invariant. This means, that if \(\psi(t, x)\) is a solution, then so is

\[
\psi(t, x) = \psi(t, x - ct)e^{icx + i|c|^2 t/2},
\]

with \(c \in \mathbb{R}^d\) some finite speed. In particular, if initially we choose \(\psi(0, x) = Q(x)\), then we obtain the so-called solitary wave solution for NLS. For \(s \neq 1\), the Galilei symmetry of the model is broken, and hence we can not expect an exact formula of the same type as in (4.2). Thus it is not obvious how an initial data of the form \(\psi_0(x) = Q(x)e^{ix}\) (we set \(c = 1\) for simplicity) will evolve. However, it can be seen in Fig. 7 that the initial hump still propagates essentially with constant velocity \(\tilde{c} \approx 1\), similar to a solitary wave. The corresponding amplitude \(|\psi(t, x)|\) oscillates around an asymptotically constant \(L^\infty\) norm, similar to the situation depicted in Fig. 6. The latter is even more visible from the \(L^\infty\) norm of the solution shown also in Fig. 7. In other words, we find that initial data of the form \(Q(x)e^{ix}\) give rise to a

![Figure 7](image-url). Time dependence of the modulus squared of the solution to the focusing fNLS equation (1.9) with \(s = 0.9\) and initial data \(\psi_0(x) = e^{ix}Q(x)\) (left). The behavior in time of the corresponding \(L^\infty\) norm is given on the right.

4.2. Perturbed ground states in the mass critical regime. The mechanism described above, i.e., that a perturbed ground state asymptotically becomes a stationary state with the same mass, is not possible for the mass critical case \(s = \frac{5}{2}\), since the \(L^2\) norm and the equation are both invariant under the rescaling (1.6). Thus it can be expected that the ground state is unstable in this case which is exactly what we observe for initial data of the form (4.1): First, for \(\alpha = 0.9\), i.e., initial data with mass smaller than the ground state, Fig. 8 shows that the solution simply decays to zero with monotonically decreasing \(L^\infty\) norm. Thereby the initial hump splits into two smaller humps which both move outwards.

However, for an \(\alpha > 1\), i.e., a perturbation with mass larger than the ground state, the solution \(\psi(t, x)\) appears to exhibit finite time blow-up, as can be seen in Fig. 9. The blow-up is also indicated by the behavior of the \(L^\infty\) norm and the \(H^1\) norm of the solution, see Fig. 10. Here, the Fourier coefficients are fitted to the asymptotic formula (3.12). As explained above, the code is stopped once \(\delta < m\),
Figure 8. Modulus squared of the solution to the mass critical focusing fNLS equation (1.9) with $s = 0.5$ and initial data $\psi_0(x) = 0.9Q(x)$.

Figure 9. Modulus squared of the solution to the mass critical focusing fNLS equation (1.9) with $s = 0.5$ and initial data $\psi_0(x) = 1.1Q(x)$.

i.e., once the singularity is closer to the real axis than the smallest distance resolved by the Fourier method. Note that we run out of resolution in Fourier space before coming sufficiently close to the presumed blow-up. This is mainly due to the large computational domain $100[-\pi, \pi]$ which was needed because of the slow decrease of the ground state solution towards infinity. Around $t = 1.0$ the resolution in Fourier space becomes insufficient, and the solution becomes incorrect as indicated by deterioration of the Fourier coefficients at a larger time. Note that the code would continue to run through and that the relative energy in this case would be still conserved to better than $10^{-9}$ at the final time. This shows that this quantity can only be used as an indicator if sufficient resolution in Fourier space is provided.
5. Numerical studies of finite-time blow-up

In this section, we will study the appearance of finite-time blow-up for solutions to the focusing cubic fNLS in $d = 1$ with rapidly decreasing initial data $\psi_0 \in S(\mathbb{R})$. The corresponding solution does not suffer from the same problems as the slowly decaying ground states, and hence gives a more reliable picture of the blow-up phenomena. Our choice of initial data is

\begin{equation}
\psi_0(x) = \beta \cosh(x) \equiv \beta \text{sech}(x), \quad \beta \in \mathbb{R},
\end{equation}

which are motivated by the soliton for the cubic NLS at $t=0$ (In particular these type of initial data have exponential decay as $|x| \to \infty$ which is preferable for our numerical studies).

5.1. Numerical reproduction of known results for NLS. Before we investigate the blow-up for fNLS, we will test our numerical methods via a study of the focusing quintic NLS $p = 2$ and septic NLS $p = 3$. For the blow-up computations in this subsection, we always use $N = 2^{17}$ Fourier modes for $x \in [10\pi, 10\pi]$ and $N_t = 50000$ time steps.

We first consider the initial data (5.1) with $\beta = 1$ for the focusing septic NLS equation, i.e. (1.9) with $s = 1$, $p = 3$ and $\gamma = -1$. This equation is mass supercritical (and energy subcritical). We find that the code breaks at $t \approx 1.4789$ due to an overflow error. The latter occurs in the computation of the nonlinearity $|\psi|^{2p} \psi$. At the last recorded time, the value of $\delta$ obtained by fitting the Fourier coefficients to the asymptotic formula (3.12) is $\delta \approx 2.4 \times 10^{-3}$ and thus more than an order of magnitude larger than the minimal resolved distance $m = 4.794 \times 10^{-4}$ in (3.13). In order to obtain the actual blow-up time, we use the optimization algorithm [31], which is accessible via Matlab as the command \texttt{fminsearch}. For $t \approx t^\star$, we then fit for the $L^\infty$ and the $\dot{H}^1$ norm of $\psi(t, \cdot)$ to the expected asymptotic behavior (3.10).

The $L^\infty$ norm thereby catches the local behavior of the solution close to blow-up, whereas the homogenous sobolev norm $\dot{H}^1$ takes into account the solution on the whole computational domain. Thus the consistency of the fitting results provides a test of the quality of the numerics. The results of the fitting can be seen in Fig. 11. Fitting $\|\partial_x \psi(t, \cdot)\|_2^2$ to $\kappa_1 \ln(t^\star - t) + \kappa_2$, we find $t^\star = 1.4789$, $\kappa_1 = -0.8197$ and $\kappa_2 = -0.3644$. Similarly, we get for $\|\psi(t, \cdot)\|_\infty$ the values $t^\star = 1.4789$, $\kappa_1 = -0.1634$ and $\kappa_2 = -0.0013$. Note the excellent agreement of the blow-up times which shows both the consistency of the fitting results and that the computation came very close...
to the blow-up. Note also the agreement with the predicted values $5/6$ respectively $1/6$ for the values of the $\kappa_1$. These values are unchanged within numerical precision if only the last 100 computed time steps are used for the fitting.

The same initial data for the mass critical quintic NLS equation in $d = 1$ lead to a breaking of the code at $t \approx 4.971$, again due to an overflow error. At the last recorded time, the value of $\delta$ obtained by fitting the Fourier coefficients to the asymptotic formula (3.12) is $\delta \approx 4.8 \times 10^{-3}$ and thus roughly an order of magnitude larger than the minimal resolved distance $m = 4.794 \times 10^{-4}$. Fitting $\|\partial_x \psi(t, \cdot)\|_2^2$ as in the supercritical case to $\kappa_1 \ln(t^*-t) + \kappa_2$, we get $t^* = 4.9711$, $\kappa_1 = -1.0077$ and $\kappa_2 = 1.3568$. Similarly, we obtain for $\|\psi(t, \cdot)\|_\infty$ the values $t^* = 4.9712$, $\kappa_1 = -0.2533$ and $\kappa_2 = 0.3426$. The agreement of the blow-up times shows again the consistency of the fitting results, and the agreement with the predicted values $1$ respectively $1/4$ for the values of the $\kappa_1$, if the scaling (3.10) is assumed.

An important question is, whether the logarithmic corrections in (3.11) can also be seen within this approach. This is unlikely, since we do not use an adaptive rescaling here for the reasons explained before (that the periodic boundary conditions lead to numerical instabilities). To test what can be seen with the present code, we do the same fitting as above for the last 100 computed time steps since the logarithmic corrections will be mainly noticeable for $t \approx t^*$. In this case we get with numerical precision the same values for $\kappa_1$ and $\kappa_2$. We denote the $L^2$ norm of the difference between the logarithm of the fitted norm and $\kappa_1 \ln(t^*-t) + \kappa_2$ as the fitting error $\Delta_2$. We find $\Delta_2 = 1.88 \times 10^{-2}$ for the $L^2$ norm of $\psi_0$ and $\Delta_2 = 4.3 \times 10^{-3}$ for the $L^\infty$ norm of $\psi$. If we fit the same norms to $\kappa_1 (\ln(t^*-t) - \ln \ln |\ln(t^*-t)|) + \kappa_2$, we get for the analogously defined fitting error $\Delta_2$ the values $3.72 \times 10^{-2}$ respectively $0.014$, i.e., higher values. Repeating the previous analysis for the last 10 computed points, the fitting errors become $\Delta_2 = 8.7 \times 10^{-3}$ respectively $6.65 \times 10^{-2}$, and $\Delta_2 = 7.7 \times 10^{-4}$ respectively $9.9 \times 10^{-3}$, i.e., a better agreement for the logarithm corrections. Thus if there is an indication of the logarithmic corrections, they can only be expected very close to the time where the code is stopped for a lack of resolution.

5.2. Finite time blow-up for fNLS. Having checked to which extent we are able to reproduce blow-up results for the usual NLS in $d = 1$, we turn now to the case of (1.9) with $s \leq \frac{1}{2}$ and initial data given by (5.1). By fitting the Fourier coefficients

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig11}
\caption{Fitting the logarithms of the $\dot{H}^1$ norm (left) and of the $L^\infty$ norm (right) of the solution to the septic NLS equation ($s = 1$) with initial data (5.1) close to the blow-up. The fitted line $\kappa_1 \ln(t^*-t) + \kappa_2$ (see the description) is given in green.}
\end{figure}
to the asymptotic formula (3.12), we find that a singularity is approaching the real axis in the complex plane for finite time, which indicates a blow-up. As discussed above, we stop the code once the value $\delta < m$ with $m$ given by (3.13). In contrast to the NLS examples with $p > 1$, no overflow error is observed in the present case, due to the smaller power of the (cubic) nonlinearity. The blow-up time is again determined via the fitting of certain norms of the solution to the expected formulae (3.10) and (3.11):

In the mass critical case $s = \frac{1}{2}$, the code is stopped at $t = 2.9413$. Fitting, as before, the square of the $\dot{H}^1$ norm of $\psi$ for the last 1000 recorded time steps to $\kappa_1 \ln(t^* - t) + \kappa_2$, we get $t^* = 2.9940$, $\kappa_1 = -2.0735$ and $\kappa_2 = 1.9783$. Similarly, we obtain for the $L^\infty$ norm of $\psi$ the values $t^* = 2.994$, $\kappa_1 = -0.5196$ and $\kappa_2 = 0.4003$. The agreement of the blow-up times provides again a check of the consistency of the fitting results. The found values for $\kappa_1$ also agree well with the predicted values $-2$ respectively $-\frac{1}{2}$, if the scaling (3.10) is assumed. To see whether there is an indication of logarithmic corrections to this formula as in (3.11), we repeat this fitting for the last 10 recorded time steps, just like in the $L^2$ critical case for $s = 1$ above. We find a fitting error $\Delta_2 = 4.5 \times 10^{-3}$ for the $\dot{H}^1$ norm and $\Delta_2 = 2.1 \times 10^{-3}$ for the $L^\infty$ norm of $\psi$. If we fit the same norms to $\kappa_1 (\ln(t^* - t) - \ln|\ln(t^* - t)|) + \kappa_2$, we get for the analogously defined fitting error $\tilde{\Delta}_2$ the values $4.8 \times 10^{-3}$ and $3.3 \times 10^{-5}$, respectively. In other words, we find essentially the same value for the $\dot{H}^1$ norm, but a much better agreement of the logarithmic correction for the $L^\infty$ norm of $\psi$ close to the blow-up. It is possible, however, that we did not get close enough to the blow-up in order for this effect to be also seen within the $\dot{H}^1$ norm, but it appears that the logarithmic correction is indeed visible locally near the blow-up.

In the mass supercritical case $s = 0.4$, we observe for the same initial data that the code is stopped at a larger time $t = 3.1347$ than in the case $s = \frac{1}{2}$. Once again we fit the $\dot{H}^1$ norm of $\psi$ for the last 1000 recorded time steps to $\kappa_1 \ln(t^* - t) + \kappa_2$ and obtain $t^* = 3.1396$, $\kappa_1 = -2.3521$ and $\kappa_2 = 2.5182$; similarly we obtain for the $L^\infty$ norm of $\psi$ the values $t^* = 3.1396$, $\kappa_1 = -0.5192$ and $\kappa_2 = 0.4441$. There is again a good agreement of the fitted blow-up times and of the values of the $\kappa_1$ with the predicted values $-2.25$ and $-\frac{1}{2}$, respectively, if the scaling (3.10) is assumed.

It is known (see, e.g., [4]) that multiplication of the initial data with a rapidly oscillating factor of the form $e^{ib|x|^2}$ with $b > 0$ introduces a defocusing effect in the standard NLS equation. Indeed, one can prove that for $b > 0$ sufficiently big, the solution to NLS exists for all $t \geq 0$, regardless of the sign of $\gamma$. Again these considerations do not directly apply in the presence of fractional derivatives. But it can be seen in Fig. 12 that the fNLS solution for $s = 0.4$ and $\psi(0, x) = e^{ix^2} \text{sech}(x)$ not only does not show blow-up as above, but displays the behavior of solutions to the defocusing fNLS equation to be studied in the later sections.

6. THE ENERGY CRITICAL AND SUPERCRITICAL REGIME

Recall that there is no energy supercritical regime for the usual NLS in $d = 1$. However, we can reach this regime in the fractional NLS (1.9) as soon as $s < \frac{1}{4}$. We will study both, the focusing and the defocusing situation in more detail. For cases where no blow-up is observed, we also trace the $\dot{H}^s(\mathbb{R})$ norm invariant under the rescaling (3.1). To this end, we consider here $s = 0.2$ for which the critical exponent is $\sigma = 0.3$, in view of (1.8). The initial data will be the same as in Section 5 above, i.e.,

$$\psi_0(x) = \beta \text{sech}(x), \quad \beta \in \mathbb{R}.$$
6.1. Finite time blow-up for energy supercritical fNLS. It is not clear, what the precise conditions on the initial data are, which lead to finite-time blow-up in the energy supercritical regime. The numerical experiments of the previous subsection seem to indicate that initial data in the vicinity of the ground state with larger mass and smaller energy than the ground state produce such a blow-up. In fact, if we study initial data with small mass, say $\psi_0 = 0.1\text{sech}(x)$, we find that the initial hump simply decays to zero as $t \to +\infty$, as can be seen in Fig. 13. The $L^\infty$ norm of the solution is monotonically decreasing and there is no indication of blow-up in this case. The scaling invariant $\dot{H}^{0.3}$ norm also appears to be bounded as can be seen in the same figure.

However, for the initial data $\psi_0 = \text{sech}(x)$, the code is stopped at the time $t = 6.0748$ since the distance between a singularity (as indicated by the Fourier coefficients via (3.12)) and the real axis is smaller than the numerical resolution.
Fitting, as before, the norm $\dot{H}^1$ norm of $\psi$ for the last 1000 time steps to $\kappa_1 \ln(t^* - t) + \kappa_2$, we get $t^* = 6.2771$, $\kappa_1 = -3.6949$ and $\kappa_2 = 8.5231$ with a fitting error $\Delta_2 \approx 10^{-2}$. Similarly we obtain for the $L^\infty$ norm of $\psi$ the values $t^* = 6.2804$, $\kappa_1 = -0.5779$ and $\kappa_2 = 1.2001$ with a fitting error $\Delta_2$ of the order of $10^{-3}$. The found values for $\kappa_1$ agree with the predicted values $-3.5$ respectively $-\frac{1}{2}$, if the scaling (3.10) is assumed. Note that the blow-up time $t^*$ is more than twice the $t^*$ found for the same initial data in the mass critical case, which seems quite surprising (as one would naively expect the blow-up time to be monotonically dependent on the choice of $s$). The agreement of the fitted blow-up times for the two norms is less good than in the mass critical case. This is due to the fact that the code did not get as close to the blow-up time as for $s = \frac{1}{2}$. It appears that considerably higher resolution would be needed in this case as is indicated by the stronger divergence of the $\dot{H}^1$ norm.

6.2. Long time behavior for defocusing energy supercritical fNLS. In Fig. 14 we show the solution to a defocusing fNLS equation (1.9) with $s = 0.9$ and initial data (5.1) with $\beta = 1$. It can be seen that the solution is simply disperses. This behavior is even more visible from the $L^\infty$ norm of the solution which is shown in the same figure. Obviously the norm is monotonically decreasing.

For weaker dispersion, i.e., smaller $s$, the situation changes, however. As can be seen in Fig. 15, for $s = 0.2 < \frac{1}{2}$, i.e. the energy supercritical regime, the initial hump splits into two humps both of which travel to spatial infinity.

The formation of the two humps can also be inferred from the $L^\infty$ norm of the solution which is shown in Fig. 16. The $L^\infty$ norm appears to become almost constant for large $t \gg 0$. An interesting quantity in this context is the scaling invariant $H^{0.3}$ since its boundedness would allow to control the solution globally in time. It can be seen that there is no indication that this norm diverges (also not for larger times than shown here). However, in comparison to the earlier numerical study of [8] for energy supercritical NLS (in $d = 5$), we do not find that the critical $H^{0.3}$ norm approaches a constant for $t \gg 0$. This is probably due to the fact that in our case, the solution decays much slower as $x \to \infty$ which prevents our numerical method from computing for even longer times. A possible way to overcome this issue is the scaling regime introduced in the next section.
7. Numerical study of the semiclassical regime

7.1. Semiclassical rescaling. A possible approach to study the long time behavior of solutions to the (dimensionless) fNLS (1.9) is by considering slowly varying initial data of the form

\[ \psi_0(x; \epsilon) = u(\epsilon x), \]

where \( \epsilon \ll 1 \) is a small semiclassical parameter and \( u \in \mathcal{S}(\mathbb{R}^d) \) is some given initial profile. As \( \epsilon \to 0 \) the initial data approaches the constant value \( u(0) \). Hence, in order to see nontrivial effects one has to wait until sufficiently long times of order \( t \sim O(1/\epsilon) \), which consequently requires to rescale the spatial variable onto macroscopically large scales \( x \sim O(1/\epsilon) \) too. In other words, we consider \( x \mapsto \tilde{x} = x \epsilon, t \mapsto \tilde{t} = t \epsilon \) and set

\[ \psi^\epsilon(\tilde{t}, \tilde{x}) = \psi(\tilde{t}/\epsilon, \tilde{x}/\epsilon), \]

where \( \epsilon \ll 1 \) is a small semiclassical parameter and \( u \in \mathcal{S}(\mathbb{R}^d) \) is some given initial profile. As \( \epsilon \to 0 \) the initial data approaches the constant value \( u(0) \). Hence, in order to see nontrivial effects one has to wait until sufficiently long times of order \( t \sim O(1/\epsilon) \), which consequently requires to rescale the spatial variable onto macroscopically large scales \( x \sim O(1/\epsilon) \) too. In other words, we consider \( x \mapsto \tilde{x} = x \epsilon, t \mapsto \tilde{t} = t \epsilon \) and set

\[ \psi^\epsilon(\tilde{t}, \tilde{x}) = \psi(\tilde{t}/\epsilon, \tilde{x}/\epsilon), \]
to obtain the following *semiclassically scaled* fNLS for the new unknown $\psi^\epsilon$, where we discard the “tildes” again for the sake of simplicity:

\[ i\epsilon \partial_t \psi^\epsilon = \frac{\epsilon^{2s}}{2} (-\Delta)^s \psi^\epsilon + \gamma |\psi^\epsilon|^2 \psi^\epsilon, \quad \psi^\epsilon(0,x) = u(x), \quad x \in \mathbb{R}^d. \]

For $\epsilon \ll 1$, the behavior of this equation describes solutions on macroscopically large space and time-scales, which justifies the name of semiclassical asymptotics. In this section we shall numerically study the behavior of $\psi^\epsilon$ for $\epsilon \ll 1$ with an initial profile given by

\[ \psi^\epsilon(0,x) \equiv u(x) = \text{sech}(x), \]

with $x \in [0,\pi]$. From the numerical point of view, the simulation of Schrödinger equations in the semiclassical regime is a formidable challenge, for which several different techniques have been developed in recent years, see the review [22] for more details.

**Remark 7.1.** In the linear case $\gamma = 0$ the classical limit $\epsilon \to 0$ can be described using the theory of Wigner measures, see [15]. Indeed, one can prove (under some mild assumptions on the initial data) that

\[ \lim_{\epsilon \to 0} \|\psi^\epsilon(t,\cdot)\|_{L^2(\mathbb{R}^d)}^2 = \int_{\mathbb{R}^d} \mu(t,x,dk), \]

where $\mu(t,\cdot,\cdot) \in \mathcal{M}_+(\mathbb{R}^d_x \times \mathbb{R}^d_k)$ is a non-negative Radon measure (the so-called Wigner measure), satisfying the following transport equation on phase space:

\[ \partial_t \mu + \nabla_k H(k) \cdot \nabla_x \mu = 0, \quad \text{in } \mathcal{D}'(\mathbb{R}^d_x \times \mathbb{R}^d_k). \]

Here, $H(k) = \frac{1}{2} |k|^{2s}$ is the associated classical Hamiltonian obtained for $\gamma = 0$. For our choice of initial data (7.2), and in $d = 1$ this yields $\mu(t,x,k) = \text{sech}^2 \phi_-(x,k)$, where $t \mapsto \phi_t$ is the phase-space flow induced by the Hamiltonian system

\[ \dot{x} = \partial_k H(k) \equiv |k|^{2s-1} \text{sgn}(k), \quad \dot{k} = -\partial_x H(k) \equiv 0. \]

Note that for $s < \frac{1}{2}$ the right hand side of the first equation becomes singular. For $s = \frac{1}{2}$, however, one obtains a hyperbolic transport with constant velocity $\text{sgn}(k) = \pm 1$.

For the classical cubic NLS ($s = 1$), an asymptotic theory for the solution as $\epsilon \to 0$ is usually based on WKB type expansions. To this end, one assumes

\[ \psi(t,x) \approx a(t,x) e^{iS(t,x)/\epsilon}, \]

where $S(t,x) \in \mathbb{R}$ is a real-valued phase function and $a(t,x) \in \mathbb{C}$ (in general) complex-valued amplitude. In the defocusing case, one can prove (see, e.g. [3] and the references therein) that as $\epsilon \to 0$, this gives a valid approximation of the exact solution $\psi^\epsilon$ provided $a,S$ are sufficiently smooth solutions of the following hydrodynamic system:

\[ \begin{aligned}
\partial_t S + \frac{1}{2} |\nabla S|^2 + \gamma |a|^2 &= 0, \\
\partial_t a + \nabla S \cdot \nabla a + \frac{\gamma}{2} \Delta S &= 0,
\end{aligned} \]

or, in terms of $\rho = |a|^2$ and $v = \nabla S$:

\[ \begin{aligned}
\partial_t v + v \cdot \nabla v + \gamma \nabla \rho &= 0, \\
\partial_t \rho + \text{div}(v \rho) &= 0.
\end{aligned} \]

Since this system in general exhibits shocks, the WKB approximation is only valid for short times $t < t_c$, where $t_c > 0$ is the time where the first shock appears (also known as caustic-onset time, or time of the first gradient catastrophe). In the focusing case, the situation is even worse, as the obtained hydrodynamic system is
found to be elliptic and thus not well-posed, see [23, 38] for some partial results in the completely integrable case \( d = p = 1 \).

**Remark 7.2.** For \( s = 1 \) the system (7.6) can be formally obtained from the so-called Madelung system in the limit \( \epsilon \to 0 \). The latter is obtained by inserting the right hand side of (7.3) into the NLS and separating real and imaginary parts, which gives

\[
\begin{align*}
\partial_t S + \frac{1}{2} |\nabla S|^2 + \gamma |a|^2 &= 0, \\
\partial_t a + \nabla S \cdot \nabla a + \frac{a}{2} \Delta S &= \epsilon^2 \Delta a.
\end{align*}
\]

This system is indeed equivalent to the NLS, provided \( a \neq 0 \). This formulation has been used in, e.g., [21] to study the semiclassical limit of defocusing NLS. In the case of fractional NLS, no such equivalent Madelung type equivalent system has yet been derived (due to the lack of an appropriate Leibnitz rule).

### 7.2. Semiclassical limit of the focusing fractional NLS equation

In this subsection we study the semiclassically scaled, focusing (cubic) fNLS equation (7.1) with \( \gamma = 1 \) and \( \epsilon \ll 1 \). For NLS (\( s = 1 \)) in \( d = 1 \) and generic initial data, it is known that the semiclassical system (7.5) exhibits a gradient catastrophe at some finite time \( 0 < t_c < +\infty \), yielding a square root type singularity in the gradient of the phase, see [10]. For \( \epsilon > 0 \), this singularity is regularized by highly oscillatory waves (the so-called dispersive shock phenomena). Indeed, one can see numerically that the square-modulus of the solution continues to grow for some time \( t > t_c \), and eventually splits into several smaller humps leading to a zone of modulated oscillations as can be seen in Fig. 17.

**Remark 7.3.** We refer to [10], [11] for more details and a conjecture concerning the asymptotic description of the solution to semiclassical NLS near \( t \sim t_c \). See also [2] for a partial proof of this conjecture.

For smaller values of \( s < 1 \) and \( \epsilon < 1 \), the dispersion gets weaker and the focusing effect of the equation becomes stronger. This leads to a higher maximum and a more “agitated” oscillatory zone after the maximal peak. It was shown in [26], that this maximal peak needs to be numerically well resolved. If this is not the case, the Fourier coefficients for the high wave numbers get polluted, which triggers the modulation instability of the focusing NLS equation. The latter phenomenon cannot be controlled even with Fourier filtering methods. Therefore we cannot reach much smaller values for \( s \) and \( \epsilon \) than used below. It would be necessary to go to higher than double precision to be able to address more extreme cases. In Fig. 17 we show the solution to the semiclassical focusing fNLS for \( \epsilon = 0.1, \ s = 0.9, \) and initial data (7.2). The computation is carried out here with \( N = 2^{16} \) Fourier modes and \( N_t = 20000 \) time steps.

The same resolution can be used to study the same situation for the slightly smaller value of \( \epsilon = 0.08 \). It can be seen in Fig. 18 that, as expected, there are more oscillations and a higher maximum in this case. To treat the solution for the same initial data with even smaller \( s = 0.8 \), we had to use \( N = 2^{18} \) Fourier modes and \( N_t = 50000 \) time steps in Fig. 18. It is clearly visible that the maximum of the solution continues to grow as expected with smaller \( s \), and that the oscillatory zone shows more humps than for the same value of \( \epsilon \), but larger \( s \). As discussed in the previous sections, a blow-up is to be expected for sufficiently small \( \epsilon \) for \( s \leq \frac{1}{2} \).
7.3. Semiclassical limit of the defocusing fractional NLS equation. In this subsection we study the semiclassical regime for defocusing fNLS equations. In the NLS case (s = 1), it is known that solutions corresponding to initial data (7.2) exhibit a gradient catastrophe at two points, here, for symmetry reasons, at $\pm x_c$. As in the case of solutions to the Hopf equation, this is a cubic singularity at the onset of the formation of a shock. For small $\epsilon > 0$, this singularity is regularized in the form of a zone of rapid modulated oscillations as in dispersive shocks of the KdV equation. The initial hump is defocused whilst the sides of the hump steepen. At a given point, oscillations form near these strong gradients.

For smaller values of $s$ and $\epsilon$, the dispersion again gets weaker which implies stronger gradients and thus more rapid oscillations. In Fig. 19 we show the solution to the semiclassical fNLS equation (7.1) for $s = 0.9$, $\epsilon = 0.1$ and initial data (7.2), which is very similar to the situation with $s = 1$. But it can already be seen here that the initial hump splits into two smaller ones, in contrast to the case $s = 1$. The computation is carried out with $N = 2^{14}$ Fourier modes and $N_t = 10^4$ time steps.

For even smaller $\epsilon$, there are much more oscillations in an otherwise identical setting as in Fig. 19, as can be seen in Fig. 20.
Figure 19. Solution to the semiclassical, defocusing fNLS equation (7.1) with $\epsilon = 0.1$, and initial data $\psi_0 = \text{sech}(x)$, on the left for $s = 1$, on the right for $s = 0.9$.

Reducing $s$ has a similar effect as can be recognized in Fig. 21 where we show the solution for the initial data (7.2) in the energy critical case $s = 0.25$. An additional effect of the smaller dispersion is that (as noted above) the initial hump splits into two humps, which are now well defined (at least before the formation of the first dispersive shock). Later in time, there appears to be a focusing effect for these two humps, as they get compressed and increase in height. If the code is run for longer times, this phenomenon continues and the code finally runs out of resolution. We also show the scaling invariant $H^\sigma$ norm in the same figure.

To address the question whether the focusing of these humps could lead eventually to the formation of a singularity as for solutions to the semiclassical system (note that global existence of regular solutions is not proven for energy supercritical fNLS), we consider the energy supercritical case $s = 0.2$ in more detail. The code is run with $N = 2^{17}$ for $x \in [\pi, \pi]$ and $N_t = 50000$ time steps for $t \in [0, 3.8]$. The solution can be seen in Fig. 22. The extreme compression of the humps is clearly visible.

The code is stopped at $t = 3.7368$ since the distance of the nearest singularity in the complex plane to the real axis as determined by fitting the Fourier coefficients to the asymptotic formula (3.12) is smaller than the smallest resolved distance in
Figure 21. Left: Solution to the semiclassical, defocusing fNLS equation (7.1) for the energy critical case $s = 0.25$, $\epsilon = 0.1$, and with initial data $\psi_0 = \text{sech}(x)$. Right: The invariant Sobolev norm (1.7); the energy of the initial data implies $\sqrt{2E/\epsilon^{2s}} \approx 0.8776$.

Figure 22. Solution to the semiclassical, defocusing fNLS equation (7.1) for the energy supercritical case $s = 0.2$, $\epsilon = 0.1$, and with initial data $\psi_0 = \text{sech}(x)$.

physical space. But as can be seen from Fig. 23, where we also show the solution at the last recorded time, the Fourier coefficients indicate that the code ran out of resolution before. In fact, the modulus of the Fourier coefficients decreases only to the order of $10^{-1}$ at $t = 3.61$, whereas it reached $10^{-6}$ for $t = 3.41$ (this implies that the numerical results in this case should be ignored for $t > 3.5$). Thus the code runs out of resolution well before a potential singularity hits the real axis. Rerunning the code with higher resolution produces the same phenomena, just at slightly later times. This indicates that the solutions indeed stays regular in this case, but is nevertheless very different from the focusing fNLS equation studied in the previous subsection. It is also different from the well-known cusps found in the case of semiclassical defocusing NLS, as can be identified using the techniques given in [29]. We finally note that the same qualitative behavior is also observed for different choices of localized initial data.
Numerical Study of Fractional NLS

Figure 23. Solution to the semiclassical, defocusing fNLS equation (7.1) for $s = 0.2$, $\epsilon = 0.1$ and the initial data $\psi_0 = \text{sech}(x)$ at $t = 3.7368$ on the left, and the corresponding Fourier coefficients on the right.

Various norms of this solution are shown in Fig. 24, where one has to bear in mind that there is a lack of resolution for the last time steps. It can be seen that the $L^\infty$ norm continues to grow (the shown oscillations might be spurious and due to finite resolution in physical space), and that there is a strong growth in the $L^2$ norm of the gradient of the solution. Whereas the strong gradients in the solution are reflected by the growth of the latter norm, there is no indication of it blowing up at a time close to the last computed time. Also the $\tilde{H}^s$ norm invariant under the rescaling (1.6) grows only moderately. This is in accordance with the conclusion above that the solution stays regular. Note that the strong compression of the humps visible in Fig. 22 does not allow us to reach the same asymptotic regime for the long time behavior of the solution as in [8] for a higher dimensional NLS equation. The reason for this is simply that the solutions decay much slower in $|x|$ in one spatial dimension, especially in the presence of fractional derivatives.

Figure 24. Time-dependence of various norms of the solution to the semiclassical, defocusing fNLS equation (7.1) for $s = 0.2$, $\epsilon = 0.1$ and the initial data $\psi_0 = \text{sech}(x)$: on the left the $L^\infty$ norm, in the middle the $L^2$ norm of the gradient, and on the right the invariant norm (1.7).

8. Conclusion

In this paper we have presented a comprehensive numerical study of various issues appearing in the context of fractional NLS equations in one spatial dimension. We have fixed the nonlinearity to be cubic and have varied the order $s$ of the fractional derivatives. This allowed to explore the competing effects of nonlinearity and dispersion in NLS systems.
Concretely we were able to numerically construct ground state solutions to the focusing fNLS equation and study their stability in certain regimes. As expected, the ground states are stable for \( s > \frac{1}{2} \) (the mass subcritical case). Perturbations of such states result in a solution which numerically displays damped oscillations around a final ground state of the same mass as the initial data. Moreover, we also find that approximate solitary wave solutions are possible despite the non-locality of the dispersion within our model. For smaller values of \( s \leq \frac{1}{2} \), the ground state is unstable both against being radiated away towards infinity and finite-time blow-up. Concerning the latter, we numerically studied the appearance of blow-up in mass and energy supercritical regimes. In the mass critical regime, we give numerical evidence for a self-similar blow-up with a profile given by the fractional ground state \( Q(x) \) and a rate close to the well-known log-log regime (as proved for mass critical NLS with \( s = 1 \) and \( \sigma = \frac{3}{2} \)).

We also studied the long time behavior of solutions in the energy critical and supercritical regime. To this end we introduced a semiclassical parameter \( \epsilon > 0 \) in the equation (7.1) and studied the corresponding asymptotic regime for \( \epsilon \ll 1 \). We found that solutions to the defocusing fNLS equation appear to stay regular in time but exhibit a surprising oscillatory structure which is much more extreme than for the associated NLS (\( s = 1 \)) case. In the focusing case, blow-up was found for values of \( s \leq \frac{1}{2} \), but there seems to be no qualitative difference between mass-supercritical and energy-supercritical blow-up.

\[ Q(x) + Q - Q^{\alpha+1} = 0 \in \mathbb{R}. \]

\[ (\Delta)^{s} Q + Q - Q^{\alpha+1} = 0 \in \mathbb{R}. \]
